PREFACE.

WE have reached another of those halting places which enable us to address ourselves directly to our readers, with less formality than belongs to the usual impersonal character which appertains to Journalism. We have, since we undertook our present editorial position, found so many courteous correspondents and able contributors amongst our readers, that we feel ourselves as addressing rather a wide circle of friends than the dim, unknown, shadowy band, which it is the fate of writers often to address, and we feel, therefore, that but few words are necessary as preface to our FIFTH VOLUME. It contains the records of a year's experience—the chronicle of a year's progress amongst photographers in every quarter of the globe. By means of the reports of meetings, contributions of papers, and the aid of correspondents, professional and amateur, we believe we have been able to keep our readers familiar with every fact of importance, materially bearing upon the interests of photography throughout the world. Whatever has conduced to the perfection of the art in scientific discovery, whatever has tended to the improvement of its various appliances, optical, chemical, and mechanical, whatever has promised to increase the range of its applications, has been, we believe, carefully noted and faithfully recorded.

A journal in the present day, however, scarcely fulfils its mission, scarcely achieves its duty, unless it is the pioneer as well as the recorder of advancement—initiating improvements as well as chronicling their progress. How far we have worthily filled this position becomes us not to decide: we have at least always discharged our duty with a full consciousness of its responsibility, fully sensible of the honour conferred upon us by the trust of our readers, and with an earnest endeavour to be truthful to that trust. By our own pen, by selecting our collaborateurs and directing their labours, we have steadily endeavoured to widen the scope of the art and its applications, to exalt its aims, to give increased prominency to its art aspects, to simplify and establish its theories, to improve its practice, to maintain its dignity whilst increasing its popularity, to give it, in short, increased value and interest for every one who pursues it, whether professionally, or as amateurs. And we have here to record our deep tribute of thanks to the multitude of friends who have aided us in our task, whether by their esteemed volunteer contributions, their valuable advice, or kind sympathy.

All our aims and intentions our readers well know, and how far also we have maintained them. It is unnecessary to enter into fresh pledges here. All that the PHOTOGRAPHIC NEWS has been, as an organ of photographers, and a faithful exponent of their art in its scientific, artistic, practical, and commercial aspects, it shall continue to be: all that it might and should be in addition, we will strive to make it, various arrangements being now in progress for giving to our next volume fresh interest. Regarding these arrangements it is only necessary to say that we shall not deem it needful or desirable to travel beyond the legitimate range of photography in search of novelty. The continually expanding character of the art in its varied relations, invests it with ever new phases of interest, and demands from the photographic journalist every year more concentrated and undivided attention. The year that is coming will, we believe, be an important one to our art, and the gage which England has thrown down to all comers in the tournament of nations, will impose important duties on conscientious journalists in every department of science, art, and literature. We promise our readers to endeavour to be worthy of our position and of their confidence, in the coming year, as we trust we have been in the past. The date at which we write permits us, in conclusion, the opportunity of wishing to each of our readers a happy Christmas and a prosperous New Year.

32, PATERNOSTER ROW, *December 24th*, 1861.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 122.—*January* 4, 1861.

OUR NEW VOLUME.

In the present volume we have, according to previous announcement, made arrangements for the appearance of a variety of original contributions, some on subjects hitherto untreated, and others on subjects but imperfectly known, as not coming within the every-day experience of the photographer. We may mention amongst those for which arrangements are completed, The Technology of Art as applied to Photography, by Mr. A. H. Wall; a series of practical papers on Instantaneous Photography, Marine Photography, Astronomical Photography, Printing Transparencies, Enlarging, Printing on Ivory, &c., &c., by Mr. Samuel Fry; Notes and Jottings, and on Lithography and Photolithography, by Mr. Hannaford; on Photographic Chemicals—their Manufacture, Adulterations, and Analysis; and on the Lime Light and its application to Photography. The majority of these articles will appear at once, and will be continued regularly. As, however, the demands on our space made by matters of current interest will not permit of the whole of the subjects appearing weekly, some of the subjects will appear at fortnightly, instead of weekly, intervals. We have reason to believe, from the correspondence we have received, that the arrangements for our new volume will be regarded with universal satisfaction amongst our numerous readers.

A GLANCE AT PHOTOGRAPHY IN 1860.

A very brief retrospect of the photographic history of the past year will be necessary here, as we presume that the majority of our readers have read the "Annals of Photography" for the year, published in our Almanac.

Notwithstanding the unprecedentedly unpropitious weather for photography which has prevailed, the year has been marked by decided progress. Whilst no startling discovery of new principles has been made, many interesting modifications and applications of known theories have come into operation; and a more widely spread and intelligent knowledge of the scientific bases and practical details of the art, has become general amongst its votaries.

With the most important improvements in processes and apparatus our readers are already familiar, and we have not space for a recapitulation. We may, however, for a moment just glance at one subject which the experience of the year has done much to bring to a satisfactory solution; but which still requires careful attention: we refer to permanent silver printing. We believe that the experience of careful and skilful photographers has resulted in a decided conviction of the permanency of silver prints when toned by the alkaline gold toning bath, and fixed and washed with care, and intelligent apprehension of the known principles appertaining to these processes. We know that many failures have occurred, both as to beauty, and permanency of results; but we feel assured that these are not necessary contingencies. As regards brilliancy of tone, the failures have chiefly arisen from imperfect preparation of the paper, or from the use of a sample unsuited to the character of the negative and to the results desired. Much depend on the original character of this unprepared paper, as may be conclusively shown: and we trust that the experiments in this direction, in which Mr. Jabez Hughes is engaged, and the results of which we shall publish when completed, will throw much light on this subject. As regards the question of permanency, we feel convinced, notwithstanding the doubts expressed by some respectable authorities, that if the manipulations are performed with judgment, the fixation effected in fresh neutral hypo of sufficient strength, and the washing properly performed, the utmost permanency is attainable. We have seen, and toned ourselves, during the last two years, some thousands of prints, and scarcely one failure in any respect not readily traceable to its cause. That some further knowledge is yet to be attained, as to the precise qualities of paper and preparation best suited to produce at will the exact quality of tone desired, we do not deny; but we deprecate the tendency to condemn or undervalue on light grounds a process at once so scientific in character and permanent in result.

One of the most gratifying features of the progress of the year is the increased attention given to the Art aspects of photography. There is, we believe, a general interest beginning to be felt amongst the more intelligent photographers in application of the principles of Art to the production of photographic pictures. Lenses and processes, however perfect, are beginning to be regarded as but the material or mechanical appliances of the art; its pencils and pigments, its paper, panels, or canvas. Whilst not undervaluing these, nor the highest manipulatory skill in using them, the importance of a knowledge of principles governing pictorial excellence is beginning to be more highly appreciated. To this end we have the satisfaction of thinking that the contributions appearing in our own columns from the pen of our talented contributor, Mr. Wall, and others, have largely contributed; and we have especial pleasure in calling attention to one of the most eloquent papers we have met with in photographic literature, on "Art-Photography—its Scope and Characteristics," which appears in the present number; and to the "Technology of Art," as applied to photography and other Art contributions, commenced in the present volume.

In this direction, largely, lies the future of photography: on this basis, in an essential degree, must the success of the professional portraitist be established. In this respect only can he distinguish himself from the herd of pests and degradations to the art, who occasionally figure in police reports as "Photographic Artists," (heaven save the mark!) for assaults upon unwary customers, whom they have inveigled by false pretences into their dens, for Sunday touting, and other practices, in contravention of law and decency. In simple, clean, sharp, mechanical photography, such "artists" may, more or less, successfully vie with respectable portraitists. But it is in higher qualities the professional artist-photographer must hope to maintain his position.

Closely allied with this aspect of photography, both in character and importance, is the advancement made in the art of photolithography and photozincography. A specimen of the latter we presented to our readers in the beginning of the year. For the purpose for which it is intended, nothing can be better; and our readers are familiar with the very large saving it effects in the cost of producing copies of the maps in the Ordnance Survey Office at Southampton. Results not inferior in merit have been produced by other distinct processes of photography: one in Vienna, on which the action of light on asphaltum is made available; and the other that of Mr. Osborne of Australia, the details of which we recently gave, in which the photogenic action of the salts of chromium, in combination with organic matter, forms the basis of the process. A specimen produced by Mr. Osborne has just been issued in the *Photographic Notes*, and is equal to anything of the kind we have seen. The most recent contributions of photography to the printing-press is the process of Herr Pretsch for surface block-printing, which is, however, as yet in its infancy. The first specimen we saw, which was printed with great care, and issued in the *Journal of the Photographic Society*, possessed many excellences, and was full of promise; the last issued specimen, in our Liverpool contemporary, was so much inferior that it tended to destroy that promise. It is, we doubt not, capable of further improvement; and if it can be made available for general subjects, Herr Pretsch will have contributed one of the most valuable improvements issued in connection with photography. M. Joubert's system of phototype, although very promising in result, being a secret, does not admit of comment. As yet none of these processes are available for the highest classes of book illustration. More is yet to be done, and we do not despair of seeing the time when photography shall have largely superseded the graver and burin.

Perhaps few things speak more encouragingly of the vitality of photography than the state of the various photographic societies; whilst a few have gone out of existence, others are starting into being, and the majority exhibit an energy and activity in the highest degree cheering.

We have not space even to glance at many of the important photographic features of the year; although interesting as celestial photography, or annoying as the unjust proceedings at South Kensington Museum. We here take leave of the past year, and hope for our readers more congenial weather, with every success, photographic and otherwise, in the year to come.

ART-PHOTOGRAPHY: ITS SCOPE AND CHARACTERISTICS.

BY. C. JABEZ HUGHES.*

PHOTOGRAPHY, hitherto, has been principally contented with representing Truth; cannot its sphere be enlarged, and may it not aspire to delineate Beauty too? All men love Beauty. The sentiment of Beauty is innate in us. It is not only a part of our nature, but one of the best parts. We have no evidence that any other creature on God's earth has the perception of Beauty but man. The poor savage, the dull boor, and the educated man, all love Beauty. The child loves Beauty, the youth and maiden dream of Beauty. The strong man toils night and day for Beauty, and the aged ones close their eyes, and look with confidence into that bright world they are hastening to, for the full realization of all their disappointed hopes of Beauty. The mother sees Beauty in her babe, children in their parents, and lovers adorn each other with a Beauty concealed from all other eyes.

And there are different kinds of Beauty; there is Material Beauty, Intellectual Beauty, and Moral Beauty. The love of Beauty is no narrow feeling; the man full of it cannot contain himself, but must communicate it to his fellows; and the ways of its expression are various. Some give utterance in

"Thoughts that breathe and words that burn:"

other seize the rude clay and solid stone, and carve enduring monuments; but the more general form of its expression is pictorial.

Man is the only animal that makes pictures, and all men love pictures. The earliest form of writing is pictures. The only universal language is pictures. Earliest history records the existence of pictures, and the child's first passion is for pictures. Civilization and pictures go hand in hand, and the more civilized men are the more they value them. "Man cannot live by bread alone," but must have pictures. Every art that man can invent is applied to increase the production of pictures. The steam-engine, printing-press, electricity, all must help to produce pictures. The child's first lesson is from a picture-book. Dry science is made interesting, and fiction more fascinating, by pictures. The more man becomes educated, the more he requires pictures; for education and pictures are indissolubly connected. The highest art and deepest science are concentrated on pictures: we paint them by Light, print them by Steam, engrave them by Electricity, and distribute them by the Railroad.

If pictures, then, exercise so powerful an influence, how highly may we estimate the greatest picture-producing power ever devised!—I mean our glorious Photography. What invention was ever more deeply appreciated, more fondly cherished, more devotedly cultivated than this child of the Sun? What art can boast in so short a time of so numerous a band of attached disciples? Others may have added more to our material wealth, but none have communicated so much pure and unalloyed good, in aiding science, assisting art, and by the humble but potent aid of exchange of portraits, ministering to and keeping alive in every part of the globe, those warm domestic and holy feelings of affection which are the very bases of our nature.

Our business just now is not with the usual applications of photography. We seek the higher forms of pictorial representation, and wish to know whether the artist-photographer may not, by the aid of the camera, as legitimately express his love of beauty, as the poet by his pen, the sculptor by his chisel, or the artist by his brush? The means are different, but the end is the same.

Permit me, before proceeding further, to make a few distinctions, to assist us in discussing our subject. I propose to divide general photography into three classes, Mechanical Photography, Art-Photography, and, for want of a better term, High-Art Photography.

* Read at a meeting of the South London Photographic Society, Dec 20, 1860.

Mechanical Photography will include all kinds of pictures which aim at a simple representation of the objects at which the camera is pointed, and will not only include all reproductions, but the great majority of portraits and landscapes. Let it be understood that I do not mean the term *mechanical* to be understood depreciatingly; on the contrary, I mean that everything that is to be depicted exactly as it is, and where all the parts are to be equally sharp and perfect, is to be included under this head. I might have used the term *literal* photography, but think the former better. This branch, for obvious reasons, will always be the most practised, and where literal unchallengable truth is required, is the only one allowable.

Art-Photography will embrace all pictures where the artist, not contented with taking things as they may naturally occur, determines to infuse his mind into them, by arranging, modifying, or otherwise disposing them, so that they may appear in a more appropriate or beautiful manner than they would have been without such interference. This class may easily embrace almost all subjects. In landscapes, the artist may select the period of the year, the condition of the weather, time of the day, point of sight, length of exposure, &c., as material agencies in modifying his picture. The same in portraiture, by arrangement of light, pose, expression, presence or absence of accessories, &c.; also in the composition of pictures, by the due attention to all the necessary parts, so as to form one harmonious whole.

High-Art Photography.—This distinction may appear presumptuous, but I feel a necessity for it, to include certain pictures which aim at higher purposes than the majority of art-photographs, and whose aim is not merely to amuse, but to instruct, purify, and ennoble.

If such distinctions as these be admitted, we can the more easily discuss the various kinds of pictures, and assign them each to their proper class.

Our more immediate object is with what I propose to call art-photographs. With many of these productions we are quite familiar, particularly those of that true artist-photographer, Rejlander. The idea of producing art-photographs is not a new one; it is almost coeval with photography itself. In 1845, Mr. Mayall, then of Philadelphia, designed and executed a series of ten pictures on daguerreotype plates, in illustration of the Lord's Prayer. This series was highly appreciated in America, and when exhibited in this country received high encomiums from the art press. In 1848 he composed a series of six, illustrative of Campbell's "Soldier's Dream." It is to be regretted that these were only on silver plates, as they were confined therefore to his own gallery, and the great merit they possessed known only to a few. Numerous other art-photographs he composed, particularly a very fine one in illustration of the words, "And this Mortal shall put on Immortality." This work, for the fineness of conception, and noble simplicity of execution, in my opinion exceeds all that has yet been produced. This gentleman, though he has precedence in point of time, has done little or nothing in this line lately, and it is to Rejlander we are mainly indebted for popular illustrations of art-photographs. Mr. Robinson has also produced some very superior productions of this class, of which his last one, "The Holiday in the Woods," is by far the most ambitious, and by many considered his best; it is certainly the largest, but there is a deep pathos and feeling about his "Fading Away," that gives that picture a far higher place in my mind than any of his other productions.

Rejlander occasionally, and Mr. Robinson often, use more than one negative to produce their pictures.

To describe this class of picture, a word has been coined—Composition-Photography. Now, I object to this word, as descriptive of what I propose to call art-photographs. It is not sufficiently definite, and is open to misconstruction, and moreover, it is descriptive rather of the means taken to produce the picture, than its nature when done.

I may be told, that "composition," in an artistic sense, means the operation of devising, arranging, modifying, and successfully carrying out the artist's conception. The idea may exist in the painter's mind, but the reducing to practice, in a proper and harmonious manner, the various parts required to form the picture, so that the idea conceived shall at last be adequately expressed—this operation, partly mental, partly physical, is what an artist will tell me is meant by composition, and that photographs produced by such means he would call Composition-Photography. Well, in an artistic sense this is right, but as the word is for photographers, they cannot be expected to understand it in this refined and technical sense, but will attach to it the plain and literal meaning, a print *composed* from different photographs.

Take a notable art-photograph, Rejlander's "Two Ways of Life," and ask an artist if that is a composition-photograph? "Most assuredly," he will say, "as much so as any painting, and a very clever composition." Now ask a prosaic photographer, "Is that a composition-photograph?" and his reply will be, "Certainly, composed from ever so many negatives, and very nicely printed-in."

Now that cannot be a very happy word, that is capable of conveying such different meanings relating to the one subject.

Again, take Lake Price's "Don Quixote in his Study," or his "Roman Festa," and ask the artist and the photographer, are these composition-photographs? The artist will exclaim, "Yes, and fine ones," while the camera-man will declare "they are nothing of the kind: they are both from single negatives, and printed all at one time."

Here I fancy I hear the man with the black fingers exclaim to the artist, "What do you know about photography? come here, and I'll show you something worth calling a composition-photograph. Here's a print five feet square, composed of twenty-five negatives, and I'll defy you to tell where one ends and the other begins. They are taken from a large map. That's what I call a composition-photograph!" Artist (with knitted brows and violent manner), "That a composition-photograph! It's no composition at all; mechanical drawing by sunlight, nothing else."

This is sufficient to show that the term composition-photography is not definite enough, and that it will be difficult for the photographic mind to separate it from the idea of printing from many negatives. Indeed, if we don't mind, we shall get into trouble and confusion with this question of printing from many negatives, by allowing mechanical ingenuity to usurp the place of artistic skill. For my own part, I don't like printing one picture from several negatives. There may be times when it cannot be avoided; but, wherever possible, it should be carefully shunned. Artistically speaking, it is false in principle, and photographically a step in the wrong direction. Its tendency is to cripple art and degrade photography. It is making the conception of the artist depend on the skill of the printer. It is a confession of weakness on the part of both, by doing in fragments what is ultimately to be represented as if done as a whole.

When an artist conceives a brilliant thought, and hastens to put it on canvas, how he sighs that he is obliged to work piecemeal, that he cannot with one sweep of his brush realise the thought in his mind. It is the proud boast of photography that it can do this. In depicting a portrait it does not begin with the head, go on with the hands, then put in the drapery, and finally the accessories: it works all at once, as a whole. This is the natural mode, and it was reserved for patchwork-photographers to discover the method of taking the head on one plate, the body on another, and the feet on a third, and then by printing them together to produce a tasteless monstrosity.

See yon lovely landscape of hill and dale, water and sky, how shall I proceed to depict it? Shall I first photograph the river, and then do the trees—next week take yon hoary old castle, and some other time the distant hills and sky, and then, by ingenious printing, fit and match them together, like a child does its toy puzzle? Or shall I uncover my lens, and with one effort seize nature with all her native charms, her local and general hues, her natural *chiaroscuro*, just as she now is, and as she never will be again?

I fancy I hear some one say, "But you cannot get this natural harmony; you may secure the landscape, but you lose the sky, or you get the sky and lose the landscape; and the argument now is, can we not print the sky into the landscape, or the landscape into the sky, and so make the photograph perfect?"

That is exactly the question, can we do this? Let us hope we can. Let us try, but bear in mind mere printing clouds into landscapes is not making perfect photographs. A fine photograph of clouds and sky is one of the most beautiful we can depict; but to join it on to a landscape, without having a most tender regard for the nature of the subject, instead of raising the photographer to the rank of an artist, will only degrade him to the level of a mechanical printer. An outcry has justly been raised against white-paper skies, but don't let us run into the opposite error of indiscriminately printing-in clouds. No sky will ever harmonize like the one that existed when the view was taken. Let the efforts then be to take the natural sky simultaneously with the landscape. In this direction lies the true progress of artistic landscape photography.

Until we make further advances in our art, we shall be troubled, especially in out-door work, with the unequal reflection of light; but let our ingenuity be exercised rather in devising means of giving short exposure to the sky, and longer to the foreground, so that they may simultaneously be produced. I think this better than, by tricks and dodges, to print-in another sky, which, under the best circumstances, can be but a sorry substitute for the natural one.

Before concluding this incomplete essay, allow me to say a few more words on Art-Photography. I feel that photography is capable of being made to minister to higher purposes than any to which it has yet aspired, and that it will as certainly take its place as a fine art as sculpture or painting. How early, depends on the earnestness, truthfulness, and intelligence of its votaries.

The tendency just now is to produce art-photographs by fragmentary portions, rather than direct and all at once.

Strictly speaking, this consideration does not lie in our province. A photographer, like an artist, is at liberty to employ what means he thinks necessary to carry out his ideas. If a picture cannot be produced by one negative, let him have two or ten; but let it be clearly understood, that these are only means to the end, and that the picture when finished must staud or fall entirely by the effects produced, and not by the means employed. When judging of a paintiug, we do not ask the artist how many sittings he took from his models, or how often he arranged his lay figure; these are the mechanical appliances of the arts—the mysteries of the printing and painting rooms.

I lay stress on these points, because I find persons dwelling too much on the beauties of an art-photograph, and praising the artist *because* he composed it from so many negatives, thus exalting too highly the mechanical instead of the artistic skill.

We have abundance of mechauical ability, it is the artistic we want to cultivate. For my own part, I am sorry to see that an artist photographer is obliged to have recourse to more than one negative, and can fancy how he must be annoyed and crippled by working in this fragmentary way.

Of two given pictures, equal in merit and design, that one is the best which is secured by the *fewest* negatives; for he is the higher artist who produces the greatest results with the smallest means. I consider it, then, rather a demerit, that a given picture should require so many negatives to produce it; it indicates a poverty of means or design, and is so far a reflection on the art, or the artist, or both; for, after all, the ultimate picture must appear as if produced from one negative. Not only are the manipulatory difficulties increased, but the risks run are very great of altogether destroying that natural harmony and chiaroscuro always present in a picture taken from one negative.

Finally, I do not think the advocacy of composition-printing tends to advance Art-Photography. It starts with putting clogs and fetters upon it. As mind is higher than matter, so is art loftier than mechanics. The artistic mind is not mechanically inclined. It is better—clearing all obstacles from his path—to allow the art-photographer free scope to his fancy, and, trammelled with few mechanical details, to give him freedom in the use of the camera aud printing frame, as the legitimate vehicles of expressing his conceptions of Beauty.

In this way only, loving our Art, can we hope to elevate it.

As Mechanical Photography deals with Material Beauty, so let Art-Photography treat with Intellectual Beauty; and when deep and earnest minds, seeking to express their ideas of Moral and Religious Beauty, employ High-Art Photography, then may we be proud of our glorious Art, and of having aided in its elevation.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

CONFIDENT that Art is now beginning to occupy no small share of attention among photographers at large; believing, with good reason, that there is amongst them an increasing desire to possess at least the more general ideas associated with its study; and well convinced by personal experience that we can best minister to such desires by marshalling our ideas on the subject under certain authorized heads, we commence these papers.

Nearly all, if not all, our terms of art have had their origin from foreign sources. Many are derived from the refined peoples of antiquity, and most of them are of Italian birth. From this cause, perhaps, as giving licence to the boldness of occasional caprice, combined with the carelessness of some writers, and the ignorance of others, the terms of art have suffered much in the clearness and importance of their popular definitions; but they are now more than ever endangered by frequent misapplication among the numerous votaries of photographic art; among whom error and misconception in reference to such nomenclature abound exceedingly.* Herein lies, we think, the more urgent necessity for such a work as the present.

The technicalities of art, it should also be remembered, had doubtless their real origin in the exigencies of the artist's noble craft; whereas, photography, must perforce adopt such terms as already exist in connection with kindred pursuits. It may, therefore, easily be imagined that in applying these technicalities to an art so novel and so strange in its various peculiarities, such terms would necessarily undergo some slight change or modification of meaning; and this being the case, it must, we think, be very desirable that such alterations—whether great or small—should be clearly expressed, in order that students may not become confused in their proper application during practice.†

For the sake of system and ready reference—as has been already explained—these articles will appear in alphabetical order. They are not intended to form a mere glossary of terms used in art, but rather to convey a series of practical

* As an illustration we may mention that we had our attention recently called to a case where, in a paper of instructions issued by an eminent photographic chemist, a statement is made to the effect that the use of a lens of long focus in a dull light is apt to produce a want of *breadth*! The term *breadth* was here manifestly confused with *vigour* or *brilliancy*, qualities which, whilst not antagonist to, are still less synonymous, with *breadth*.

† A very glaring instance of this is pointed out in Mr. Hughes' eloquent and excellent paper on "Art Photography" in the present number.

instructions in the real value, purport, and significance of the technicalities defined, in their application to photography.

Having shown why we believed our labour in this view would not be unwelcome or useless to our readers, and explained our purpose in regard to them, we have now only to add that if the abilities we devote to the task be of the humblest, we will endeavour to make good the deficiency by increased care and study in carrying out our design.

Abozzo.—A term used by the Italian Painters, to indicate the first, or dead-colouring, of a picture. As this was usually executed in one or two colours only, the appearance of such a sketch would closely resemble that of a warm-toned photograph. This fact is a strong argument against such writers as have asserted the impossibility of anything like real artistic colouring being obtained when applied over the hues of a photograph; which, by the by, may be toned to a colour precisely similar to that in which the great Titian usually executed his *abozzo*, and upon which, in some seven or eight after paintings, he wrought up his inimitable effects of colour.*

Accessories.—Objects introduced into a picture as auxiliary to the general effect. Inartistic photographers are very apt to make use of such rather for qualities peculiar to the objects themselves, than with a view to their effect in carrying out the rules of pictorial composition. While the injudicious use of accessories is sure to destroy the artistic value of the photograph,† their importance to the complete effect when introduced with good taste and proper judgment, cannot well be overrated, apart from the opportunities they afford the colourist of bringing forward the more attractive qualities of his art, or the purpose they assist in telling some tale in connection with the principal subject. Accessories are used to secure breadth of chiaroscuro; to fill up unostentatiously such portions as would appear bare and naked without them; to preserve the balance of parts, and the proper arrangement of lines. They should never divert attention by their prominence, or otherwise attractive character, from the more important group or figure of the piece. They should not be numerous; and they should be so arranged that their several powers concentrate into a focus just where pictorial excellence demands that the principal effect should exist.

Accidentals.—Used to indicate artistic effects of a transient or accidental character. An eye to recognise with skill, and appliances to secure, the numerous effects of nature—which, being due to some transient atmospheric influence, some chance display of nature's least common aspects, or some purely artificial influence, are termed accidental—rank among the landscape photographer's most desirable acquirements. No finer illustration of this can be pointed out than the results produced, photographically, by the thousand transient effects to be observed upon the surface of water, which will sometimes render one picture taken but a few seconds after another, and with precisely the same exposure, to be so palpably superior, in both an artistic and photographic sense, that the mere mechanical operator, attributing the result to some abrupt, unknown, and mysterious change in his chemicals, almost worships the blind chance to which he attributes it; whilst he slights that knowledge, which would enable him to command the valuable result, whenever the natural chance to which it was due might arise. Those effects of nature which are termed accidentals in a picture, should, however, receive from the photographic art-student a very large share of serious attention, whether his studies be pursued for landscape, portraiture, or other pictorial branches of his art.

Accidental Lights.—Lights which owe their existence to some accidental circumstances of a natural or artificial character; or such peculiar effects as may arise from gleams of light penetrating an accidental aperture, or proceeding from a fire, a candle, or some supernatural source—as in the celebrated "notte" of Corregio, in which the light emanates not only from the ordinary source, but also from the infant Saviour's body. Accidental lights are extremely pleasing and picturesque when judiciously introduced, and have then an important effect in the chiaroscuro, composition, and sentiment of a picture. They frequently fall within the camera artist's field of practice, and should be studiously looked for. A very effective accidental light may frequently be secured by a method recommended by one of our own correspondents, of forcing aside the boughs of trees*; by which means a stream of light may be admitted into some wild nook of forest scenery, some foliage-overshadowed cavern, or some otherwise obscure thicket of trees; thus giving a romantic or picturesque charm to a subject which might otherwise be dull, tame, and ineffective. Many charming qualities of this nature are overlooked by mechanical operators, simply because they have never understood the great pictorial value of such accidental effects.

Accidental Points.—Vanishing points in linear perspective, which do not fall upon the line of the horizon.

Accidental Colour.—In looking fixedly at any one colour the eye soon begins to conjure up another colour which is the proper contrasting or complimentary hue of the first: thus if you place a red wafer upon a sheet of white paper, and look at it stedfastly, upon turning the eye to another part of the surface a faint green wafer will become visible—the eye having itself supplied the accidental, or contrasting, or complimentary colour. Colourists should remember this fact, because in turning from working upon any one colour for a certain length of time, and begining to be employed upon another, the last would for a while be modified by the accidental colour of the first. For instance—suppose you are painting a scarlet coat, and turn from it to the flesh, the latter—until the eye has recovered its former condition—will appear too green, and also, by contrast, too pale.

Action.—That which has no small influence in giving life or animation to a picture. It is usual, in giving a definition of this word, to draw a distinction between it and motion; and such a distinction is really necessary—art can but suggest motion—those who attempt to force its powers in this direction, too frequently render themselves ridiculous. That which never moves should not be represented in absolute motion. Motion which has just ceased, or which is on the eve of just commencing, may be legitimately and advantageously adopted, but one step beyond is fraught with serious danger. Just imagine a figure represented in the act of walking, with one foot suspended as it were in the air, and ask yourself, if such a representation would not be a gross infraction of good taste. Photographs of figures taken in rapid motion have been executed—but merely as curiosities, to illustrate the rapidity of a certain process—in which sense they are interesting and valuable. I do not deny that some eminent masters have combated this difficulty, and, to a certain extent, conquered it; but the example is not one I should dare to recommend. Action is very significant of life, and is the source of that gracefulness of outline which cannot be overrated. In portraiture, much may be secured in the way of character, by varieties of position and attitude indicating action, but care should be observed in avoiding the slightest appearance of affectation. See further remarks under the heads of Attitude, Motion, &c., in the forthcoming portions of these papers.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATIONS, AND ANALYLSIS.

IN accordance with a promise contained in our last number, we now commence a series of articles, having for their object a complete practical guide to one of the most important branches of scientific photography. We have been induced to undertake them for several reasons; apart from the numerous enquiries which we have received from our con-

* A hint some of our artistic colourists may find worth their taking.

† "When accessories are introduced without any meaning or motive, and in direct opposition to the sentiment of the subject, it is an instance of bad taste"—*Mrs. Jamieson.*

* See page 103, vol. iv., PHOTOGRAPHIC NEWS.

tinental and colonial subscribers, asking for information on the best means of preparing the various chemicals which are with difficulty obtained pure, even if they are to be had at all, except in large towns,* we think that the diffusion of a little chemical knowledge on special subjects will be of great service to the great bulk of our subscribers, many of whom are, to our knowledge, continuing, year after year, the unconscious victims of the grossest adulteration in the materials they use, simply because the very easy methods of purification, and testing for falsifications, have never been properly pointed out to them. We do not know a single instance of real eminence in our art having been obtained without its being accompanied by, and in great measure due to the possession of a certain amount of chemical skill in the handling of the more simple tests and re-agents; whilst it would be easy to point to scores, who, possessing the highest artistic knowledge and manipulative skill, are fettered and bound to an inferior level by their inability to tell when their chemicals have the necessary degree of purity, or, knowing them to be adulterated, how to detect and remove the sophistication.

We purpose, therefore, to pass in detail over the ordinary contents of the photographer's store of chemicals. It will be impossible, on many occasions, to avoid entering into apparently trivial details, but in chemistry detail is everything, and when addressing those whom we must assume to be in want of the knowledge we are endeavouring to impart, it would only defeat our object to confine our remarks to the surface. Each substance will accordingly be taken *seriatim*. The best method or methods of *preparation* will first be fully entered into, the *properties* will next be described, after which will be given the various *adulterations*, with which it is likely the commercial article may be intentionally or accidentally contaminated; this will naturally be followed by the methods of *testing* and *purification*, whilst a short account of the *uses* of the substance will form a fitting conclusion. The whole will, when completed, form a complete handbook to this branch of photography, and will in many cases be sufficient to save the operator going to the expense of purchasing a larger treatise on the subject.

The first substance in order of importance, of which we shall treat, is

Nitrate of Silver.

Preparation.—The preparation of this important salt will usually require to be effected from silver coin, or from the photographer's silver residues; we will take the former case first, leaving the latter to be treated of when we describe the best method of converting residues into pure silver. The first thing to be done in the manufacture of nitrate of silver from coin (which contains silver, copper, and sometimes a trace of gold), is to dissolve the coin in nitric acid; for this purpose, take as new and heavy a silver coin as possible, (for the nominal value of old and new coin being the same, the photographer may as well get as much silver for his money as possible), it will also be better to have the coin of as small a denomination as possible; for instance, suppose five shillingsworth of coin were intended to be dissolved, there would be an advantage in taking twenty silver threepenny pieces (new), rather than one five shilling piece. First of all, it will be necessary to remove all the dirt and grease from the surface of the coins, which may be effected by well brushing them in hot soap and water containing some soda dissolved in it. After well washing with distilled water, and wiping with a piece of fine clean linen, they may be considered as sufficiently clean. All the vessels and utensils employed in subsequent operations must be cleaned in like manner. Next take a sound china (not earthenware) breakfast cup, a quarter fill it with pure concentrated nitric acid, add to it about one ounce of distilled water, and then place in the coins a few at a time. Arrange a glass funnel, upside down, so that it just rests inside the cup but not low enough down to touch the liquid; the object of this is to prevent particles of the solution from being projected out of the vessel and thereby being lost, owing to the brisk effervescence which will soon take place. Place the cup and funnel on the hob of a grate in which there is a moderate fire, for the double purpose of warming, and hastening the reaction, and of carrying off the deleterious vapours up the chimney. It will also be advisable to place the cup on a clean plate for the purpose of preventing the heat from the hob from acting too suddenly upon the cup. A lively effervescence will soon take place, torrents of a poisonous and disagreeably smelling red gas will be evolved, and the coin will gradually disappear, forming a blue solution. If the evolution of gas seems likely to cease before the coin has entirely disappeared, a little more nitric acid may be added, taking care to add to the acid, previously, about one-fourth its bulk of distilled water. When the action has entirely ceased the solution will present a clear blue colour, with perhaps a few black or brown particles settling to the bottom, these will be metallic gold, and may be collected at a subsequent stage of the operation. The next part of the process will be to get rid of the excess of nitric acid which has unavoidably been added; for this purpose take the outer vessel of a common glue-pot or some similar vessel which will allow the cup containing the solution of the coin, to rest on the top, low in the vessel, but without slipping in. The handle of the cup will be here found to be considerably in the way; it will therefore be as well to choose, in the first instance, a cup from which this useful appendage has previously been removed. Half fill the outer vessel with water, and then place it over a source of heat—a gas air-flame will be the best, but a common fire will do in default of this—and let the water boil briskly. The funnel must now be removed, its inner surface having been rinsed with distilled water into the cup, and the heating over this extempore water bath continued until acid vapours cease to come out of the cup, and the contents of the latter have become quite dry and inodorous. The cup may then be removed from the water bath, and about two ounces of distilled water added. It will now be a pure solution of the mixed nitrates of silver and copper; and the next operation will be to remove the latter impurity from it. Two methods may be adopted for this purpose; and as they will each be useful under circumstances where some of the materials necessary for the other process may not be at hand, we think it best to give each of them in succession:—

1. Pour the contents of the cup into a wide-mouthed stoppered bottle, of about a pint capacity, add to it half a pint of water and a solution of purified common salt, until the white precipitate, which will immediately be thrown down, is not increased by a further addition of salt solution; well shake the bottle, and allow it to stand and settle for a few minutes. The addition of a little weak nitric acid will be found to facilitate the settling, and, therefore, if it has been previously decided to adopt this method of purification, the whole of the acid need not have been driven off in the water bath. When the precipitate has quite settled, pour off the clear liquid (first testing it with salt to see if all the silver has been removed from it), and then fill up the bottle with distilled water, shake, allow it to settle, and repeat the above operations for several successive times until the addition of weak ammonia to the clear liquid, after it has been poured off, does not cause it to assume a blue tint. Next, add to the precipitate remaining in the bottle some large, clean, wrought-iron nails, and half an ounce of very weak sulphuric acid; allow it

* Where chemicals can be obtained pure, we by no means recommend the photographer to manufacture his own; but the knowledge conveyed in these articles of the nature of the materials used, and the methods of ascertaining their purity, will in all cases be found valuable. To our foreign readers, they will, however, prove pre-eminently important. One of several letters recently received from India, speaking of such a series, remarks, "It would be a perfect treasure to us exiles, thousands of miles from any chemists. It is most disheartening to find many exported chemicals nothing but rubbish; and I know several scientific amateurs have been driven to make their own nitrate of silver, chloride of gold, &c., &c., in despair of producing a picture unless they did so, or procured chemicals direct from home, a work of five or six months."

to remain for twenty-four hours, when the whole mass will be found to be converted into a dark grey powder: this will be metallic silver. Remove the remains of the nails from the powder, wash well first with dilute sulphuric acid, and then with distilled water in the manner above recommended, until the solution ceases to turn blue litmus paper red, when the residue will be pure metallic silver, which will only require to be dissolved in nitric acid in the same manner, and with the same precautions recommended above, when the dry residue left in the teacup will be pure dry nitrate of silver.

Notes and Jottings.

No. II.

Experiments on Dry Plate Photography suggested.—Remarks on "Cocking" the Camera.

In the report of the Experimental Committee of the South London Photographic Society on the dry processes, Mr. Borchert alludes to the effects of what he terms "cleansing liquids" on the plates. He employs a solution of ammonia to dissolve out all salts of silver in the film, excepting the iodide and the bromide. By acting on this suggestion, we are inclined to believe that some experiments of an interesting nature might be conducted. At all events we purpose directing our attention this way, and as many of the readers of this journal are fond of experimentalism, we invite them to take up the subject and favour us with the result, in the hope that we might advance another step towards the elucidation of this important question. We throw out the following hints for those who may wish to pursue the matter:—

After washing the sensitized plate in common water, a portion of the free nitrate of silver is thrown down as chloride, &c.:

By means of solution of ammonia (different degrees of strength may be tried), and afterwards washing in distilled water, we get rid of this chloride, &c., together with the sundry indefinite organic silver salts which are formed when old collodion is used, leaving in the film only iodide, or iodide and bromide.

From this point we start afresh, bearing in mind that some other salt of silver should be present besides the iodide.

Re-dipping in a weak silver bath—say 3 to 5 gr. to the oz.—draining, treating with a solution of chloride of sodium, and washing, we have a film with only iodide and chloride of silver in it.

In similar manner we can procure the presence of any other salt in lieu of the chloride. Now let us prepare a few plates on this principle, coat with some preservative, gelatine for instance, and when quite dry, expose, and carefully note the comparative results as regards sensitiveness, density, &c., so as to arrive at answers to the following questions:—

What are the properties of a film containing only iodide and chloride of silver? It is generally stated that the chloride produces want of intensity, but that the plates keep well.

In like manner, what is the effect of bromide with the iodide?

The same with acetate, or citrate, which are usually stated to give greater intensity?

Many other questions will naturally arise, but those given will serve to point the direction to which experiments should tend.

Amongst other questions mooted in Mr. Rothwell's paper, read at the November meeting of the parent society, is that of the effect obtained by "cocking" the camera. Every photographer has at times been unwillingly obliged to esort to this "dodge," when his point of view has chanced to necessitate it. In landscapes of a rural character, the distortion thus produced is comparatively of slight consequence; but when we come to views in which are perpendicular lines, in a row of houses for instance, the case is different, the perpendiculars converge so that the buildings are represented wider at the bottom than at the top. It is true that to the eye the perpendiculars do appear to converge, nevertheless, for certain reasons which we need not enter on here, they must not be so rendered on a *plane surface parallel to those perpendiculars.*

The plan to avoid "cocking" most familiar to the photographer is, first, to get the camera perfectly level, and then to move up the lens by means of a sliding front. Another method is to use a swing back; in which case the camera may be "cocked," but the ground glass must be kept in a perpendicular position.

The ordinary swing back involves the employment of too cumbersome an apparatus for the out-door work of an amateur. Mr. Shadbolt has, however, lately introduced the plan of moving the lens instead of the back of the camera, and thus, by a little ingenuity, almost any apparatus can be made to equal, indeed, in our opinion, to surpass the old stage-coach swing back. A camera, manufactured by Mr. Meagher, was recently described in these pages, with a very simple contrivance to obtain the same effect.

Many of our "practical" readers don't understand, and don't care to bother themselves about the rules of perspective; but we would nevertheless ask them to note this single one, that *when the plane of delineation, otherwise the ground glass, is kept strictly parallel to the building to be drawn, the perpendicular and horizontal lines in the object will be projected as perpendicular and horizontal on the the focussing screen.* Hence the following conclusion:—

By first levelling the camera, the plane of delineation is placed parallel to the object to be drawn; and keeping the body of the camera stationary, we may move the lens in any direction, supposing it mounted after Mr. Shadbolt's plan, without producing distortion of the perpendicular and horizontal lines.

It will, however, be obvious that as some parts of the ground glass will be more or less distant from the proper focus of the lens, the smallest possible stop must be used in order to get sharpness. Michael Hannaford.

RESEARCHES ON THE ACTION OF LIGHT ON BODIES.—Intensity of Emitted Light.

BY M. EDM. BECQUEREL.

When a body is struck by a bundle of luminous rays, the molecules of this body are put into a state of vibration, and independently of the rays reflected and transmitted, they produce heat, light, sometimes chemical action, and perhaps also other molecular effects than those now under consideration, and which are not immediately appreciable. But on account of their diversity, these effects can be only partially studied, and if the calorific actions have formed the subject of important labours, those of phosphorescence have not, nor even taken that direction.

Having in previous essays studied the composition of the light emitted by bodies by virtue of their own action, and after the previous influence of luminous radiation, it became important to compare the intensity of this light with that of the active rays in the various circumstances of the experiments.

When a body, after being submitted to the action of light, is placed in obscurity, the intensity of the light it then emits immediately decreases until the molecular equilibrium is established as before insolation. But the question is, in what manner this extinction is produced independently of the refrangibility of the rays emitted? Are all bodies submitted to the same laws? What is the total action received by each body when the exciting luminous intensity of a given refrangibility changes within determined limits? On the other hand, the molecular state of a body does not change the composition, but only causes the intensity of the light emitted by this body to vary, by virtue of its own particular action, we may ask what are the molecular changes which can thus modify the state of the bodies? Such are the important questions which the use of the phosphoroscope permits us to put, and which are analogous, which have treated of cooling and of the quantities of heat which bodies can absorb when submitted to the action of calorific radiation; these questions concern the molecular constitution of bodies, and give valuable indications as to the manner in which the action of light is communicated to the molecules of matter, and consequently upon the luminous agent itself.

I first occupied myself with the construction of a photometer, which enabled me to compare the luminous intensities of bodies placed in the phosphoroscope; this apparatus, previously described, is founded on the effects of double refraction; its use, together with that of different phosphoroscopes described in my previous labours, have led me to the following conclusions:—

1st. When an impressionable body is submitted to the action of light, during this action it acquires after, generally, a very short time—but which depends on the luminous intensity, and the nature of the body—a state of equilibrium, in virtue of which it emits rays, *the intensity is in proportion to the intensity of the exciting rays.*

2nd. The intensity of the light, apart from its colour, does not exceed one or two millionths of the intensity of the exciting light; it will be much less with bodies that are but slightly impressionable.

3rd. When a body, after a previous insolation, is suddenly placed in obscurity, it emits rays, the intensity of which decreases more or less rapidly according to the nature of the body.

When the emission of the perceptible rays is of short duration, and generally less than a second of time, the law according to which the loss of the light is effected is such that the difference between the logarithms of the luminous intensities, taken at different times after the origin of the distinction, is sensibly proportional to the difference of these same times, whatever be the intensity of the exciting light.

This conclusion can also be expressed by saying that the velocity of the extinction is independent of the intensity of the incident light, and proportional to the intensity of the light emitted, and as the law which appears to follow the luminous extinction of the body is the same as that of the cooling of the heated bodies, when the difference of their temperature and that of the ambient air is very small.

4th. The measure of the velocity of the loss of light permits our determining for a certain number of bodies, *the relation of their emissive power to their capacity for light.* With alumina this relation remains palpably constant, whatever be the molecular state, whether the body be crystallized, melted, or pulverized, and although the maximum intensity of the light emitted at the commencement of the extinction be very different.

The law of extinction permits also of determining for the bodies comprised in the preceding category (3rd conclusion) the total quantity of emitted light, that is, the sum of the action received by the body for a given intensity of the incident rays.

5th. When the impressionable body, suddenly placed in obscurity, assumes different tints in succession, that is to say, that the differently refrangible rays are of unequal duration (*Ex.:* diamond, fluoride of calcium, &c.), and that the luminous emission is of a certain duration and exceeds a second of time (*Ex.:* terrous alkaline, sulphides, &c.), the preceding law is no longer applicable. It is possible that the difference which exists between the results observed and those deduced from calculation, according to the law enounced in the third conclusion, are due to the differently refrangibles, so that the rays of the same colour emitted by the body, have unequal durations, and consequently different velocities of extinction. In all cases, between certain limits, the results of the experiments are very well represented by means of an empirical formula; $i^m (t + c) = c$, in which i is the intensity of the light emitted after a time; t, that which is emitted at the origin of the extinction being:—1. c a constant coefficient, and m an exponent which varies between $\frac{1}{2}$ and 1, according to the nature of the body.

6th. According to preceding results, we find that for substances which give a luminous emission of long duration, the velocity of the loss of this light varies more rapidly with the intensity of this light than in bodies in which the persistence is of short duration, and that between the limits of the experiments this velocity is evidently proportional to a power of luminous intensity comprised between $\frac{3}{2}$ and 2. The formula indicated above permits of calculating also what is the total quantity of light emitted or absorbed in giving rise to the effects of phosphorescence here studied.

We can only explain the long duration during which these substances shine by saying that they receive a greater amount of the action of the exterior light than do those bodies which extinguish it rapidly.

7th. The results of experiments made with bodies which emit light in obscurity during a long period of time, permit of our showing with what a marvellous faculty the organ of vision is endowed, in that it can distinguish and compare the slightest variation of intensity in the feeblest light.

If we take as a term of comparison, the intensity of solar light, when the sun is highest above the horizon, at the period of the summer solstice, the sky being clear, we then find that luminous green sulphide of strontium, placed suddenly in the dark after being insolated, emits luminous rays of less and less intensity, and which may also be compared with an artificial light after an hour and a half. After the lapse of this time, the intensity of the rays emitted is to that of the incident solar rays, as 1 : 10″.

Beyond this limit direct comparison is become impossible, but we still continue to perceive light during more than a day, although during this interval of time the intensity of the rays emitted by the insolated solar body has always been diminishing. We can, nevertheless, value approximatingly the feeble intensity of the rays emitted: if we suppose that the solar rays are attenuated so as to have no more than a millionth of their original intensity, in this state they will be ten million times more intense than their light, which is still distinct after a sojourn of the sulphide of strontium thirty hours in darkness. Phosphorus, also, continues luminous after this interval of time, but it is impossible to follow in a satisfactory manner the changes it subsequently exhibits.

These results show how far we can go in the study of the light emitted by bodies, even when the effects are very feeble, and between what distant limits the organ of vision is impressionable, and can compare the effects it perceives.

8th. The action of heat upon bodies rendered luminous by insolation is manifested temporarily or permanently; its temporary action consists in this, that by the elevation of the temperature, the refrangibility like the intensity of the light emitted after insolation changes, and in that the luminous effects diminish, and even cease, commencing at a certain degree. It seems that the causes which tend to scatter the molecules of the bodies, each enfeeble the power they possess of emitting rays by its own action after insolation, as on the other hand we know that gases and fluids, except under special circumstances, do not generally give rise to appreciable effects.

Heat may also act by modifying solid bodies in a permanent manner, and in this case, the action of an elevated temperature increases the intensity of the light emitted after insolation, when this body has resumed the ambient temperature.

9th. The facts hitherto observed, show that the *intensity* of the light emitted by a body when it has been exposed to light, is essentially variable, and depends on a molecular arrangement, which varies according to circumstances which we cannot always appreciate; but the *composition* of the light emitted, together with the law of its emission, remain on the contrary, constant for the same body, and depend on the nature of the latter. This constancy proves that the phenomenon of luminous emission, by its own action, is a phenomenon depending essentially on the nature of the body: and that it is not possible to refer some of the effects observed to a mixture of foreign substances. Moreover, the effects exhibited by crystalline bodies obtained at low temperatures, and always identical with each other, effects which are such that the intensity and the composition of the light remain alike, place this assertion beyond doubt.

10th. It has been assumed thus far that the exciting luminous rays fall perpendicularly upon the surface of the body; but if the rays are more or less inclined, then the intensity of the transmitted rays vary according to known laws: the luminous effects produced by bodies after insolation vary proportionally between the same limits, and as before demonstrated. I intend in the course of these researches to give my attention again to the absorbing power of bodies for light, as well as the modifications which these bodies can undergo by means of mechanical or physical effects, so as to exhibit an emission of rays varying in composition and in intensity.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 2nd January 1861.

To whom the honour of first applying collodion to photography is due, is a matter of dispute, which it is desirable should be settled once and for all. It lies between the late Mr. Scott Archer and Mons. Le Gray. In searching the annals of photography, M. Humbart de Molard has met with certain data, which would seem to substantiate M. Le Gray's claim to having made the first suggestion of applying collodion; and, as this array of facts possesses at the present time unusual interest, I may be permitted to quote them.

1849. In M. Le Gray's *Traité*, published in this year, p. 90, is the following passage:—

"I also obtain a very good negative paper with the following alcoholic solution:

§ 34	Alcohol, pure or 36° ...	1000 parts
	Collodion	10 „
	Iodide of potassium ...	10 „
	Cyanide of potassium ...	1 „ ."

1850 (June). M. Le Gray's pamphlet, p. 42, Appendix:

"I am working at the present time a process *on glass* with methylfluohydric ether, fluoride of soda and potassium dissolved in alcohol at 40°, mixed with sulphuric ether, and then saturated with collodion. I next produce a reaction with acetonitrate of silver, and I obtain a picture in twenty seconds in the shade. I develope the image with a very dilute solution of sulphate of iron with great rapidity. Ammonia, bromide of potassium, exhibit very great variations in promptitude. As soon as my experiments are completed, I shall publish the results in an appendix. The application to the glass is very easy.

"The same reagents employed with albumen and dextrine also give very prompt and excellent results.

"I have also experimented with a mucillage produced by a fucus, which seems to me very promising.

"I hope soon to be able to obtain a portrait in three or four seconds."

This pamphlet was translated and published in London in 1850.

In 1851. *Art Journal* for July. Mr. Horne makes a communication respecting the obtaining photographic pictures on collodion by Mr. Fry, to whom the idea of the process is attributed.

On the 20th of Nov. 1851, Mr. Scott Archer made his first communication to the *Athenæum*, and on the 20th of Dec. following he writes again, stating that he has perfected the process by using pyrogallic acid as a developing agent; but this suggestion had been made by M. Regnault, in *La Lumière*, Feb. 9, 1850.

In 1852, *Athenæum*, Jan. 3. Messrs. Fry and Archer dispute with each other the priority of applying collodion to photography.

In March (1852), Mr. Bingham published a supplement to his *Photogenic Manipulation*, in which he maintains *his* claim to priority in the application of collodion against both Messrs. Fry and Archer, and states, that if his results were not at first satisfactory, it was owing to his not having employed pyrogallic acid as a developing agent as advised by M. Archer.

Therefore, if documentary evidence be of any value, the honour of first applying collodion to photography is unquestionably due to M. Le Gray. If it be asked why he allowed his discovery to fall into abeyance? he answers, that at the time of making it he received a commission from the French Government to make a photographic tour in the Holy Land, and that during his absence his suggestion was adopted by others, while he was necessarily confined to the waxed paper process.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting was held on the evening of Wednesday, the 26th of December, at Myddelton Hall. Mr. SHADBOLT presided.

The minutes of the previous meeting were read and confirmed.

Mr. SAMUEL BOURNE, of Nottingham, a gentlemen with whose exquisite productions many photographers are familiar, was proposed and elected a member of the society. Two very fine photographs by Mr. Bourne were exhibited by Mr. Nicholson; one an architectural picture, the other a large vignetted landscape, consisting of wood and water, a scene in Dovedale, was one of the finest and most artistic photographs we have seen, and elicited much admiration.

The CHAIRMAN called attention to the photograph selected for presentation among the members. The picture is a 10×8 by Wilson, and is entitled "The Mill." As a photograph it is faultless, and as a picture possesses much merit, marred, however, in our estimation by the number of straight lines and stiff angles in the mill, which gives the picture its name, and which forms a prominent object in the foreground.

In the absence of any paper for reading or discussion, the meeting resolved itself very literally into what a contemporary recently styled all photographic societies—a "gossiping club." The conversation first turned on the Fothergill process, by which the negatives were taken from which Mr. Bourne's specimens were produced.

Mr. NICHOLSON remarked that Mr. Bourne used chloride in his albumen, and notwithstanding that Mr. Shadbolt had objected to its use, derived from it the most satisfactory results.

The CHAIRMAN remarked that his objection to a chloride was only relative; not that he regarded a chloride as bad, but that he thought a citrate or phosphate for the same purpose was better. It was impossible, however, to speak of one element in a process without relation to the whole. Much depended on the collodion used and the presence or absence of a bromide in its preparation.

Mr. NICHOLSON remarked, in relation to some observations on washing, that Mr. Bourne washed a ten by eight plate fifteen minutes.

Mr. G. WHARTON SIMPSON asked if that washing was before the application of the albumen or after, as its importance entirely depended on that point.

Mr. NICHOLSON said it was before the application of the albumen, and another unlimited washing afterwards.

Mr. HILL remarked that Dr. Ryley had denied the possibility of obtaining a picture if all the free nitrate were washed away before the application of albumen.

The Chairman said that much would depend on the presence of a bromide in the collodion. If thorough washing immediately after sensitizing were given to a plate coated with simply iodized collodion, a good negative, would not be obtained.

Mr. Simpson observed that in that case, at all events the sensitiveness would be very much diminished.

After some further conversation on the subject,

Mr. Simpson called attention to a curious fact in connection with the keeping of collodio-albumen plates, the details of which he had learnt from Mr. Ackland, at Messrs. Horne and Thornthwaite's, where he had seen some transparencies printed from negatives. The details had appeared in The Photographic News. (See p. 408 in our last volume.)

The Chairman said he did not think decomposition was chiefly brought about by high temperature, unless there was also a good deal of moisture present.

Mr. Simpson was aware that moisture would materially facilitate decomposition; but high temperature alone, would, in the course of time, he thought, usually assist in the deterioration of an excited plate. An excited collodio-albumen plate would usually keep better in winter, when the temperature was low, than in summer, when it was warm, and generally dry, than in winter.

Mr. Hill remarked that Mr. Moens had been successful with collodio-albumen plates, and found them keep well during his trip up the Mediterranean.

After some further observations the subject dropped, and another topic of conversation was started by

Mr. Hill, who said he had brought some specimens of albumenized paper, which had caused him great difficulty. Since the new method of preparing paper came into operation he had not met with any samples of paper so satisfactory as those prepared for the old process, and he had had several cases of "mealiness" occur. He perceived this mealiness in some of Mayall's portraits of the royal family. He found also that the albumen came off in some cases, and in one case, the albumen had came off altogether. He had sensitized the paper in a new bath of 65 grains to one oz. of water, slightly acid. Measly red spots sometimes made their appearance, which he thought was owing to the removal of part of the albumen.

The Chairman asked whether it was an established fact that there was a new method of preparing the paper?

Mr. Hill said it was acknowledged by those who sold it, that they had a new method of preparing the paper for the alkaline gold toning process. The reason for the defect was alleged to be the use of too much soda in the toning bath; but he had tried phosphates with no better result.

Mr. Simpson said, Mr. Hughes contended that there was nothing new in the method of preparation, but that any difference existing was due to the paper itself.

The Chairman thought Mr. Hughes had not established that.

The Chairman remarked that Mr. Sutton had been recently drawing attention to what he called a new method of albumenizing, by the addition of acetic acid. That was no novelty, for a year or two ago he had himself drawn attention to that method. It was not new then, for in 1854 and 1855 the Printing Committee of the London Photographic Society endeavoured to ascertain the effect of the introduction of various substances into the albumen for the purpose of getting an even coating of albumen on the paper. The result, in his opinion, was that the introduction of acetic acid was highly detrimental instead of beneficial, whereas the introduction of ammonia materially assisted in getting a good even film. This was the natural result, for ammonia being an alkaline fluid, increased the fluidity of the albumen, and being volatile, was, in the process of drying, got rid of; whereas acetic acid uniting with the alkali in the albumen formed a stable salt.

Mr. Simpson observed that it was odd that Mr. Sutton should call this method a new one, because some time ago, if his memory served him rightly, that gentleman had given the same method for obtaining an even coating and avoiding streakiness.*

The Chairman said the fact was that amateurs must albumenize their own paper, and show the way first of all, and then they would get professional albumenizers to do it commercially.

Mr. Lander said he had met with mealiness, but not through the albumen leaving the paper.

Mr. Hill showed one sample in which there was considerable loss of surface after exciting, but no apparent removal of albumen.

Mr. Simpson said that might be owing to the removal of the artificial surface given by the rolling.

The Chairman said that was an additional objection to rolling. He asked whether Mr. Simpson had ever tried acetic acid with the paper?

Mr. Simpson stated that he had used paper that smelt of it, but he had perceived no bad effect. Some of his friends had used acetic acid to get rid of the streakiness, but had not succeeded in doing so. It might be that too small a quantity had been used.

Mr. Hill observed that many of Mayall's and Claudet's *cartes des visite* showed signs of mealiness.

Mr. Simpson said he had a very strong suspicion that they were not toned by the alkaline gold toning process, as some of them were turning yellow already.

Mr. Hill.—Some are turning green. It was said that if the alkaline gold toning process were used these mealy marks would not occur.

Mr. Simpson said another point to be remembered was, that it was not always known by whom the pictures exhibited and sold were done, as the originals were frequently copied, and the copies sold as originals.

Mr. Hill said he had received a letter from a friend at Port Natal, relative to using arrowroot as a preservative. He dissolved a portion of arrowroot in boiling water, to which he added alcohol, and he then used it in exactly the same way as the Fothergill process: it answered very well.

Mr. Simpson said several similar substances had been tried with success.

The Chairman said there was another subject they might take into consideration—Mr. Heisch's recommendation to retain the old toning bath instead of the alkaline gold toning process. Mr. Heisch said, in the first place, that the latter could not be better than the former, because pictures toned by it faded. But he had omitted to say, at the same time, that even when thoroughly washed many pictures toned by the old gold and hyposulphite of soda process also faded. That could not be proved with regard to the alkaline gold toning process.

Mr. Hill attributed the fading experienced in the alkaline gold toning process to errors in the fixing, and not to the toning.

Mr. Simpson thought it was an error to suppose Mr. Heisch considered the old one best. Mr. Heisch only said he was not sure that the new process was better than the old. All that he had proved, however, was, that certain gold toned prints had faded, but he did not prove what had occasioned the fading. Mr. Heisch said that the carbonate of soda and chloride of gold were introduced, whilst in the texture of the paper, into the hyposulphite of soda, and that the decomposition would take place as much in that way as in the old process.

The Chairman did not consider Mr. Heisch's reasoning good, because it did not at all follow that the same results would follow when the substances came into contact in so different a manner from that in which they did in the old process. Everybody knew the difference between pouring the gold into the hypo and the hypo into the gold.

Mr. Simpson observed that chloride of gold would not cause that decomposition which set free the destructive element, sulphur, it was the presence of acid in the chloride that produced that effect. Very likely the fading referred to was occasioned by want of care in the manipulation. Fresh hyposulphite of soda ought to be used, not that charged with nitrate of silver.

Mr. Hill said Mr. Heisch appeared to consider the old process more permanent.

Mr. Simpson.—Mr. Heisch merely suggested the question, as to whether it had been given up without sufficient consideration.

After some further remarks on toning with iodine, which the Chairman remarked gave a tone but was not permanent, a paper by Mr. Hughes was announced for the next meeting, and the proceedings terminated.

---

* We find on reference to the number of *Photographic Notes* alluded to, what we suspected at the time, but could not assert in the absence of any immediate means of verification, that there was a slight misapprehension on this subject: Mr. Sutton does not bring this forward now as *new*, but as important, and not well known.

Photographic Notes and Queries.

The Albumen Dry Process.

Sir,—I beg to thank you for the insertion of my letter in your number of November 30, and I am obliged to your correspondents for their assistance. The frosted marks which appeared on my plates were visible immediately on leaving the bath, and therefore did not arise from the causes suggested by Mr. Russell and "An Amateur." I found the solution of my difficulty in Mr. Cramb's explanation. I was using an albumen too highly iodized for the strength of the bath, and by reducing the quantity of iodide I have once more perfect plates.

Permit me too add a few remarks on this process, and the "Taupenot" process. This latter is generally classed as a collodion process in which albumen is introduced as a preservative. I think in its original form it was clearly an albumen process, where the collodion plays a nearly inactive part in the formation of the image. This seems to be borne out by the fact that the result is nearly the same whether the collodion is iodized or not; and also that all the operations excepting the final exciting in the acid nitrate bath can be conducted in broad daylight. I do not pretend that either of these methods is suited to produce the *best* pictures, but good pictures will in either case result. Now with Messrs. Petschler and Mann's method of manipulation, and with Dr. Ryley's hot water variation, no picture whatever would result under similar circumstances, *i.e.*, with uniodized collodion, or working in daylight; therefore, I think these methods cannot be considered properly, as they have been hitherto termed, "modifications of the Fothergill process," which is, in the proper sense of the term, "a collodion dry process."

On the Continent, dry processes with collodion are comparatively but little used; wet collodion, paper, or albumen are mostly employed for out-of-door photography abroad. There can be no doubt that wet collodion is the medium with which the most perfect pictures can be produced. Next to this comes albumen.

It is difficult to conceive, in a country like this, where there are so many first-class photographers, who aim at producing the highest effects their art is capable of, that dry process which is the most capable of rendering them should be so generally neglected, that its practice should form a rare exception. But I am quite assured of this, that it has never been *properly* tried, and when judged upon its merits, laid aside for any dry process involving the use of collodion, therefore I am inclined to believe that its neglect arises from photographers generally being unacquainted with its qualities, or entertaining an erroneous idea of the ease and certainty of its manipulation. I am strengthened in this belief from the extensive employment of the "Taupenot" process, (which, of all other dry processes, I consider approaches nearest in excellence of results to the albumen process). The manipulations for "Taupenot's" are more complicated and numerous than those of any other dry prosess with collodion, and the sensitive plates have no great keeping qualities, yet the process is more used than any other, *because the resulting pictures are superior.* And if it were well ascertained that with a simpler manipulation, a cheaper material and equal certainty, a still higher class of effect could be attained, I think the "albumen dry process," which fulfils all these conditions would be very extensively practised.

I will now compare the "Taupenot" and the "albumen" processes in the various stages, based on my own experience of each.

Preparation of the Coating Material.—Here, at the outset, the comparison is much in favour of "the albumen." Prepared by nature, a constant compound, it may be procured ready for use, in the meanest village of the civilized world, alike at the command of the country photographer as of the dweller in cities: cheap, clean, invariable. In addition to this material, the "Taupenot" requires also collodion, the preparation of which is uncertain and difficult, variable in quality, unstable, and costly, to be procured only at certain centres, or to be manufactured by the photographer at a great expenditure of time; in either case without any certainty of uniformity of action.

Coating and Sensitizing.—An idea appears to prevail that coating a glass plate with albumen is attended with more difficulty than coating with collodion; this is not the case. If the albumen be not less than three days old it will flow evenly and easily, requiring no more skill than collodion; and if the excess be poured off into a second measure and strained through sponge or flannel before using again, a perfectly clean plate is always attainable, with greater certainty than with collodion as it is generally handled, by pouring off the excess back into the bottle in use. The "albumen" has one coating: the "Taupenot" has two. The "albumen" has one sensitizing, one bath solution, one washing, one drying; of each of these, also, the "Taupenot" has two. Therefore, in the preparation, the "albumen" is simpler than the "Taupenot."

Keeping Qualities.—I have never kept "albumen" plates longer than a month, but they are quite unimpaired in that time, and I see no reason why, when they are deprived of all the free nitrate by a chloride, they should not keep for a much more considerable period. I find that the limit of time for *the best results* on a "Taupenot" plate is about three weeks: others have succeeded in keeping them longer, but I gather that this is a very general experience.

Exposure.—I am less able to give an opinion on this part of the subject than on the rest, as my experience scarcely coincides with what I read respecting the sensitiveness of the "Taupenot" plates. I find it variously stated that an exposure of 15, 20, or 30 seconds for "Taupenot" plates, with a stereoscope landscape lens, is sufficient for a good negative. I rarely can take a satisfactory picture by that process, with a stereo lens and pea-stop, under 60 seconds, and I should say that the average was nearer 1½ minutes. This also I find to be the average necessary exposure for an "albumen" plate, with the same lens. I have no doubt that in the hands of those who work the "Taupenot," more rapidly than I, the "albumen" would work at the same increased rate, as the various means employed to accelerate the one process are equally applicable to the other.

Development of the Image.—Gallic acid, pyrogallic acid, or iron may be used for both processes; but with all of these the "albumen" plate, will bear more prolonged development than the "Taupenot," and no matter how long the action of the reducing agent is continued on the "albumen" plate, the parts where no light has impinged, will remain totally colourless and clean; and the solution will not be decomposed, so that it has not to be renewed. The picture also with the "albumen" never requires to be strengthened afterwards by other means.

The Picture.—I unhesitatingly assert that the picture obtainable upon "albumen" dry plates is only second to "wet collodion," and very little inferior; and that the "Taupenot" process as generally practised, is nearly as good, but not quite.

I fear I have far outrun the limits of your patience and that of your readers, but I think it is useful that the qualities of "albumen" should be better known, and that end will be best gained by publicly discussing and comparing its merits with those of other processes.

If what I have written should induce any of your readers to lock up their collodion bottles for a week, and give albumen a fair trial, I am convinced that they will not be in a hurry to return to the former in any form of *dry process* for out-of-door landscape photography.—I am, yours faithfully, F. Richards

A Hint to Amateur Mechanics.

Mr. Editor,—In reference to the answer given in your last number to G. G., on the subject of what he terms, "pluffing up," he and other of your amateur mechanics may feel a hint from a brother chip of some experience, useful.

The source of the evil complained of is in the tendency of the grain of all woods, and especially soft ones to be rubbed down in planing, however sharp the tools may be, though of course, the duller the plane the worse will be the effect, and where a file is used, as is frequently the case in fancy work, it is still worse.

The remedy is easy: before putting on the polish or varnish as the case may be, wet the surface slightly with hot water and a sponge, this will cause the sunk grain to swell up, or, as it is technically called, "to be raised," when dry, rub down the raised grain with fine glass-paper, rubbing as much as possible in a direction meeting the raised particles; repeat this till the grain no longer rises, when the finest polished surface can be produced.

In very thin articles it is sometimes of advantage in order to prevent warping, to raise the grain with the varnish or polish, rubbing down as before, but it is much more difficult to get a good surface in this way.

The softer mahoganies and walnut wood, both much in use for photographic purposes, are particularly liable to the evil G. G. appears to have met with.

An Amateur Mechanic and Photographer.

Talk in the Studio.

The Proposed International Exhibition for 1862.—This may now be regarded as a positively coming event. Most of the eminent manufacturers of the Continent are preparing for it, and those of our own manufacturing districts feel that they cannot afford to neglect the opportunity. Some 670 names are now on the guarantee list, at the head of which stands that of the Prince Consort for £10,000. The site is fixed on the estate of H. M.'s Commissioners of 1851, at South Kensington.

The New Bronze Coin.—It may surprise our readers to learn that, from one press only, not less than sixty of these are produced in a minute.

The New R.A.—Mr. G. G. Scott has been elected at the Royal Academy in the room of Sir Charles Barry.

Signing the Treaty of Peace at Pekin.—A photograph of this scene was secured by Signor Beato, the mandarins very willingly remaining still for the purpose. The great quantity of red and dark purple in the decorations of the species of shed under which the affair took place, and in the costumes of the Chinese must have been disadvantageous.

Backgrounds.—An operator of eminence informs us that one of the best means for obtaining varities of light and shade in his background is to have it so arranged with cords and pulleys that it can be sloped one way or the other at any angle, thus securing either a soft gradation of light, or of dark from the top downwards, according to the light or dark character of the object to be relieved.

A Glorious Failure.—We are happy to inform our readers that the proposed formation of an asylum for the orphans of artists, although funds were very liberally forthcoming, has turned out a failure, being relinquished for this very sufficient reason—*there are no orphans of artists requiring such a charity!*

Stothard.—The works of this very eminent artist will be exhibited by his son, Mr. Robert Stothard, early in the Spring.

"An Honourable Member."—The member for Brighton, Mr. White, whom our esteemed friend Mr. Hughes would certainly denounce as uncivilized, has recently been misleading the working men of Plymouth by rampant denunciations of government art-patronage, stating, among other strange and novel things, that the Prince Consort has distributed among his own personal favourites no less than £78,000, "extracted out of the pockets of the working classes." Truly White is black in the eye of all truth-lovers and art-appreciators.

Somewhat Alarming—Hot-Water Process.—In a recent lecture upon photography, delivered by our contributor, Mr. Wall, the following amusing anecdote was told. Our readers are perfectly aware that it is a practice with some of our operators to expedite the washing process by using hot water. A certain Mrs. G—, a timid, nervous, and very absurdly suspicious old lady, had sat for her portrait, which was promised for a certain day. Now, it so happened that, from the unpropitious state of the weather the print was only taken out of the pressure-frame an hour or so before the ancient dame came puffing up the stairs. Just as she reached the landing-place of the first flight, the angry operator called out loudly to his neglectful printer—"Now, ——, look alive, *take hold of that old Mrs. G—, and shove her into the boiling water!*" I leave you to imagine, said the lecturer, with what intense horror the poor old lady hurried tremblingly down the stairs, and her glorious sensation of safety and delight when she found herself once more in the street.

Photographing on Wood.—A very beautifull engraving produced by a new process of photographing on wood has been published as an illustration to a work translated from the German and entitled "Lyra Germanica." It is a copy of Flaxman's celebrated *basso-relievo* "Deliver us from Evil," and was printed and engraved by Mr. Bolton from Mr. Leighton's negative.

Rock Inscriptions.—Mr. Bentley announces a new work called "Sinai Photographed." The rock inscriptions which are supposed to have been executed by the Israelites who came out of Egypt.

PHOTOGRAPHIC MEETINGS IN JANUARY.

London Photographic Society	Tuesday, 8th.
South London	Thursday, 17th.
North London	Wednesday, 30th.
Blackheath	Monday, 21st.
Edinburgh	Tuesday, 8th.
Birmingham	Tuesday, 29th.
Chorlton	Wednesday, 9th.

To Correspondents.

B.—There is no fault in the toning of the specimen sent, nor indeed could the fault be in the toning bath since you state that the print is flat and feeble on first coming from the printing frame. You may hold it as a rule that if the print lacks vigour then, no subsequent treatment will make it brilliant. We think you must be in error in one of the two points, either the negative lacks vigour and intensity, or the sensitizing bath is very weak. Neither the paper nor the toning appear at fault. 2. It is purely a matter of taste whether albumenized or plain paper be used for portraits, and tastes will differ. Some of the finest results we have seen lately have been on arrow-root paper. 3. For a dark background sheeting calico painted a suitable grey tint, either in distemper, or in oil and "flatted."

Juvenis.—The best plan is always to use fresh hypo for fixing, of a strength of not less than fifteen or twenty per cent. 2. A print only partially fixed will generally show some opaque-looking patches on holding it up to the light; these consist of undissolved hyposulphite of silver. 3. Too frequent application of citric acid to decolourize the silver bath, would undoubtly make it acid, by the formation of citrate of silver, and the liberation of nitric acid. This may be neutralized with carbonate of soda. Remember, however, there is another evil to be avoided, the frequent addition of citric acid is a very wasteful process: the citrate of silver is a tribasic salt, and for every part of citric acid added, three parts of silver are taken from the bath to combine with it. If, however, instead of filtering each time, and removing the excess of citrate of silver, it be shaken up each time the solution is returned to the bottle, and then allowed to subside, and the clear solution carefully decanted off, when required for use, it will, we apprehend, serve to decolourize the bath several times. Try the plan suggested by Mr. Fry, in our pages some weeks ago.

Walter Woodbury.—The account of your interesting trip shall appear.

Charles Shone.—The information as to the grinding and turning of a speculum for a telescope, would occupy more space than we can afford. We must refer you to an optician.

F. J. G.—Thanks for your hints. The passage to which you refer, was misplaced, by mistake, in a few copies

An Amateur.—You will find an excellent formula for the manufacture of collodion, suitable for either wet or dry processes, in the Photographic News Almanac for 1861. The cost of a collodion filter is, we believe, about five shillings. It may be obtained through most photographic houses. Careful decanting, after sufficient subsidence, will be found, generally, to answer the purpose.

J. G. L.—1. Members are elected in the London Photographic Society b hallot. You must be proposed by one member who knows you, and seconded by another. The entrance fee is one guinea, and the annual subscription one guinea. The annual meeting is in February. You will receive every particular on writing to the secretary. 2. In applying the *Sochnee* varnish, and all spirit varnishes, the plate must be warmed gently, and the varnish applied whilst it is warm. It must then be held near the fire until it is set. 3. Opal glass will not injure the bath; but it is too opaque for transparencies, except where bright artificial light is used. 4. We shall shortly have some articles on printing transparencies. 5. If the stereo negatives are taken with a twin lens camera, they or the prints must be cut and transposed. 6. There is no need to add ammonia to albumen, for coating the glass, prior to the application of collodion, but it will not be injurious as the ammonia will evaporate as the albumen dries. Your sugestion regarding the volume shall receive due attention.

J. Brown.—1. Your silver bath must now, if we understand you rightly, contain fifty or sixty grains to the ounce, a most unmanageable strength; and the iodide of silver having been probably precipitated during its treatment, you find that a coated plate instead of obtaining silver from immersion in the bath, is robbed of its iodine. Saturate the bath with iodide of silver, by leaving a large coated plate or two in for a short time, and dilute the bath to a strength of about 35 or 40 grains, and you will probably find all work satisfactory. 2. You may without risk add your collodion films to your silver residues. 3. You can buy a plate of looking glass better than you can make it.

F. E. G.—Give your negatives a final wash with distilled water before drying. Try another sample of varnish, and keep the varnished negatives as dry as possible. It sometimes happens that negatives are sadly impoverished by varnishing. Where a crystal varnish has been used, it is easily removed; but spirit varnish presents more difficulty. You may try to remove it with strong alcohol. Your only resource is to use a very strong silver bath to prepare your paper, and print by diffused light; you may get a little more vigour by this means. Regarding the sale of your slides, we cannot help you further than suggesting application to the various wholesale houses whose advertisements you may see from time to time. We believe the market is very full at present. Possibly by trying another sample of collodion, you may get the intensity you require; or you may add a little acetate of silver to the bath. We shall have pleasure in seeing your photographs; but fear that the demands upon our time will preclude the possibility of our entering into any lengthened comment upon them.

Fix.—You will obtain "depth of focus" by stopping down your lens.

X. Y.—The acetate of iron gives more intensity than the sulphate. You may use, in its preparation, either acetate of soda, ammonia, potash, or lead. The latter will require filtering.

J. S., Longton.—We purchased the brown paper to which we referred for backgrounds, at a paperhanger's shop in the Euston Road; the name and number we do not remember. The price, if we remember aright, was threepence per yard; the width was a yard and half; and any length could be had. We presume it is kept by paper-hangers generally.

H. T. B.—As your letter only arrives on the day of going to press, and requires a little consideration, our answer must be delayed until next week

A Constant Subscr.—See article on the manufacture and purification of photographic chemicals, in the present number.

Many articles in type, amongst which are the letters of Fairplay and others, are compelled, for want of space to stand over until next week.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32 Paternoster Row, London.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 123.—January 11, 1861.

VISITING CARD PORTRAITS.

We had recently the pleasure of inspecting some very charming specimens of the fashionable *cartes des visite*, or album portraits, which for delicacy, roundness, and brilliancy we have never seen surpassed. In examining these beautiful productions we were convinced that they owed their peculiar qualities rather to the artistic acquirements of their producer, than to any secret method of manipulation or peculiarities of process, and meeting the gentleman by whom they were taken—Mr. Lacy, of the Isle of Wight—at Mr. Wall's studio, we were gratified to find such a conviction verified. After posing his sitter, this artist's first care is to obtain such an arrangement of chiaroscuro as is consistent both with the peculiarities of his process, and the demands of artistic rules; no pains being regarded thrown away if they tend to secure good pictorial results.

One side of his glass room has a window of ribbed glass, through which a slightly diffused light falls upon the model. On the other side a much weaker and more diffused light finds its way through ground glass,* and, acting in the character of reflected light, penetrates and softens the deeper cast shadows, and gives a tender delicacy to those parts which retire from the stronger light on the other side. Although in the model the amount of shade may appear too much decreased by this method of illumination, the well-known tendency of photography to exaggerate the depth and intensity of the shadows fully makes up for such deficiency in the negative, and the resulting pictures possess an amount of roundness and relief, combined with delicacy, which every photographer of taste must very highly appreciate.

The soft gradation and tenderness of light and shade obtained by the above method is pre-eminently adapted for ladies' portraits, but where deeper shades and more vigorous half-tones are rendered desirable by the altered character of his subject, Mr. Lacy simply draws a curtain over the ground glass, and thus deepens the shadows by decreasing that which may, for the sake of explanation only, be called the reflected light.

In the course of a very interesting conversation, Mr. Lacy pointed out how many photographers frequently give a universally unpleasant expression to all their portraits, by simply using too strong and too direct a top light. The principal muscles which govern expression—the zygomaticus major and minor—under these circumstances give rise to strong deep shadows in a downward direction from the nostrils, and the angles of the mouth. The corners of the lips being lost in these dark shades, and these dark shades being thrown at an angle downwards, the latter appear really to belong to the lips, and the result is a lugubrious or sullen expression, which, combining with the deep dark masses in which the eyes are nearly lost, and the consequently apparent depression of the brows, horrify and shock sitters into strong denunciations of "those horrible photographs," and wound their self-love in a very unpardonable, unnecessary, and unmerciful manner.

The developing and intensifying processes used in producing the negatives, from which these exquisite pictures were obtained, somewhat surprised us; not because the method was novel or uncommon; but because we have rarely found it used from choice, being generally resorted to as a makeshift or succedaneum, where manipulatory skill is limited, or materials are insufficient, to produce a satisfactory result by the usual negative process: we refer to the use of bichloride of mercury and iodine. Mr. Lacy, however, uses this proces from choice, believing that it yields special qualities—peculiar sharpness and detail, so important in small pictures—unattainable by other methods.

His explanation of the rationale of this effect is as follows:—wherever density is obtained by an accumulated deposit of silver on the image, a certain amount of delicacy and sharpness is lost, the result being similar to what would be produced by moistening a very fine, sharply cut seal or cameo, and covering it with powder. However fine the powder or dust might be, a loss of sharpness would be the result, as the powder would adhere laterally as well as vertically, and thus thicken and destroy fine lines. By intensifying with mercury Mr. Lacy conceives he only obtains a vertical deposit which does not interfere in any degree with the delicacy and sharpness of the finest details. This question may be open to consideration, and might be decided by the aid of the microscope. The points to be determined by such an examination would be, whether, in the first place, the deposit of mercury be more strictly vertical than that of silver; and in the next place whether the molecules constituting the mercurial deposit are finer than those which constitute the silver deposit. Whether this be the case or not, there is no doubt but that in the next process of intensifying—which is effected rather by changing the colour than increasing the density, the mercurial deposit being turned yellow by means of iodine—the effect is obtained there without in any degree rendering the deposit coarser or less delicate and sharp, and it is to this fact, perhaps, rather than to much difference between the character of the silver and mercurial deposit, that the delicacy in the result is due.

Every one is familiar with the superior sharpness of albumen negatives; and this we are disposed to regard as largely due to the fact, that intensity is obtained rather by the non-actinic colour of the deposit, than by its accumulated thickness.

It must not be supposed that in the use of bichloride of mercury as an intensifying agent, the process usually known as "converting positives into negatives" is involved. Converted positives rarely yield satisfactory prints, the common result being bald, and flat, without detail or modelling. These pictures are exquisitely round and full of half-tone. Sufficient exposure is given to bring out every detail with full vigour: the pictures are then developed with a strong solution of iron, about fifty grains to the ounce, with a proportionate amount of acetic acid. When thoroughly developed by one application of this developer they are, after fixing and washing, intensified by bichloride of mercury, followed by a solution of iodide of potassium.

In giving this formula we would not be understood as recommending it for general use, as it is beset by many dangers. For the guidance of those who are desirous of trying it we would add one or two cautions. Unless judgment and skill guide its use, the results will inevitably be unsatisfactory. Sufficient exposure and development must be given in the first instance to ensure the perfect rendering of detail, or hardness and flatness must ensue. A very dilute solution of iodide of potassium must be used, or stains, &c., from unequal action of the iodine will occur. Better still, perhaps, will be the use of the iodine and mercury in one solution. Make a solution of bichloride of mercury, about twenty grains to the ounce, without any hydrochloric acid. To this add, by a drop or two at a time, a saturated solution of iodide of potassium, shaking the bottle each

* Or glass painted by a method to be found at page 226 of our last volume.

time until the precipitate of red iodide of mercury is dissolved. When sufficient is added, a portion of the red precipitate will remain undissolved, and the supernatant liquid is ready for use. If any tendency to stains or unequal action be found, the solution may be diluted with water. Finally varnish with a good bodied spirit varnish, so as to prevent, effectually, any contact with the excited paper and the mercurial deposit, or the prints will be spoiled, especially if the contact be long, from slow printing. This is important, and a "crystal" varnish, made from dammar in benzole, will be found an insufficient protection.

To return to Mr. Lacy's pictures, he uses a quarter-plate lens, *well stopped down to secure modelling;* but, as he himself says, "it is not to *lenses or processes only that we must look for any amount of pictorial success, but pre-eminently to the principles of art, more particularly such as regulate the proper arrangement of light and shade.*" A remark which, illustrated as it was, by the eloquent arguments of his own beautiful productions, we can but re-echo in these pages for the benefit of our practical readers.

DIALOGUE SKETCHES.—No. 5.—Nature's Art.

[From a "Photographer's Common-place Book."]

"Painting, like all other liberal arts, is reducible in a great measure, to certain generally received rules and precepts. And though these precepts, and perhaps all others that could be given, are alone (that is without some portion of genius) insufficient to produce a good artist; yet they will almost at all times prevent a man from being a bad one. They are the reflections of the greatest masters. They point out those rocks the student should avoid; and are, therefore, indispensible to his success. They facilitate his labours, and direct him in the shortest and surest road to perfection. They refine his taste, teach him to discover the truly beautiful in nature or art, and strengthen and confirm his judgment."

When one quotes another writer it is only right and proper to append that writer's name thereto; but from whence I copied the above extract into my Common-place Book, it don't say, and I don't know; so please to take it as a poor, nameless orphan of a quotation, which may belong to some mighty "somebody," or some poor, forgotten "nobody;" but of which you now know all that I can tell.

"Have you wet or dry plates?" said Lovetruth. "Wet," replied Process, and then we abruptly departed. As they have been waiting for us three weeks, I think it is time we rejoined them.

* * * *

Here they are then, just pulling up their "gallant steed" at the spot Process has selected for commencing operations.

Process.—Wo-o-o, Bob! Well, here we are; what do you think of the spot?

Lovetruth.—It is a charming one, indeed.

Process.—There's such a variety of scenery, you see. If you want water, there's a fine piece gleaming out among the foliage yonder. If you want trees, what can be finer than these clumps and groups, scattered so plentifully about us? Or, if you prefer distance, there's miles of it to be had from the top of that fine eminence. Now for the apparatus.

Lovetruth.—There's my picture [pointing]. Do you see the broad mass of shadow transparently veiling that beautifully varied group of trees yonder, against which a graceful birch-tree, in a gleam of soft light, stands so prominently out; and beyond which trees and hills retire behind the beautiful atmospheric curtains, until they melt as it were into the horizon, thus uniting sky and landscape into one gloriously harmonious whole?

Process.—Yes; but are you not afraid of so much shadow?

Lovetruth.—Shadow—the source of power and variety, contrast and brilliancy, breadth and repose; the very soul, as it were, of the picturesque—afraid of it; no! faith not I.

Process.—I so frequently find failures in attempts to secure a proper amount of detail in associated lights and shades, that I must confess that *I* am afraid of it. I have tried all processes for one which will render the obscure and the lighted portions of a picture with equal truth; and although I have *sometimes*, by *a mere chance*, been successful, I have far more frequently failed. The best method *I* know for the treatment of a subject containing much shadow, is to adopt a collodion containing a bromide, expose with great nicety in regard to time, and use an iron developer.

Lovetruth.—You remind me of a visit I once made, at our friend Newart's request, to a photographic meeting in connection with one of your societies. Upon this occasion several exquisitely beautiful photographs were exhibited, full of great artistic merit and eloquently expressive of the refined taste and high intellectual labour which had created them. Although, in themselves, these contained full evidence of all which constituted their great superiority to the general run of such productions, everybody present appeared to insist upon regarding them as the result of efforts purely mechanical, so that I heard no questions asked beyond these —"Whose collodion?" "How iodized?" "With what developer?" and "What sized stop?" and above all "With what *lens*?" and "By what *process?*" As if, forsooth, these mechanical means, in themselves, constituted the sole end of a photographer's ambition.

Process.—Surely, you don't deny the importance of such considerations?

Lovetruth.—No more than I deny the importance of th glorious press which produced the first printed copy of that grand old book, the Bible; although, it strikes me, the divine character of the Book itself would be none the better understood, or appreciated by merely studying the type in which its pages are "set up."

Process.—But what do you mean? If the process I have named won't secure an artistic picture, what process will?

Lovetruth.—I have seen genuine pictures produced by nearly every process I have ever heard of.

Process.—Where does the secret lie, then? In the lens?

Lovetruth.—No, in the operator. Let me illustrate my meaning. I have, in the view I am just going to photograph a specimen of nature's art, or in other words, of the quality painters term a breadth of chiaroscuro.

Process.—Which means, I think, the separation of the lights and shadows into separate masses, so as to avoid a spotty appearance.

Lovetruth.—Yes; providing you do not mean such an arrangement as I have sometimes seen described as breadth, in which one black mass of almost uniform density contrasts another light one with almost as little gradation. In the view I pointed out yonder, you will perceive that although the lights and more delicate half-tones, are all grouped about the middle ground and distance, and the shadows and darker tones are confined to the mass of delicately veiled foliage more immediately in the foreground, there is sufficient light carried into the one by that softly illuminated birch-tree, and of dark into the other by that distant group of trees, to constitute that which is one of the most important elements of breadth, viz., unity.

Process.—Excuse me; I am too eager for work to enter into that which is only theoretical; and besides which, I am really anxious to know by what *process* you contrive to get shadows in your photographs?

Lovetruth.—By what you will perhaps call no process at all, for it is by the aid of what you have just termed "only theory."

Process.—Well I can't understand you at all, Lovetruth, but go on.

Lovetruth.—And yet my meaning is simple enough. So simple indeed, that if your brains were not so crowded with lenses and processes, as to blind you to everything apart from them, you must at once discover it. Say your are taking the view before us. You use your bromised collodion, and expose with your usual care, timing the exposure to the quality of collodion and class of developer you are working with. Do not under-expose, so that whilst you are endeavouring to force out those details which give the shadows transparency, you quite bury all detail in the lights. You use an iron developer, I believe; if you subsequently intensify with pyro and silver, you can, by a little management, give a little more vigour to that part of the plate which requires it. As to the quality of unity, the birch and that group of rather distant trees in the light, which are sure to come out more or less dark whether they be in light or not, will secure that, and your "mere theory" thus becomes of no little practical value. Do you understand me now?

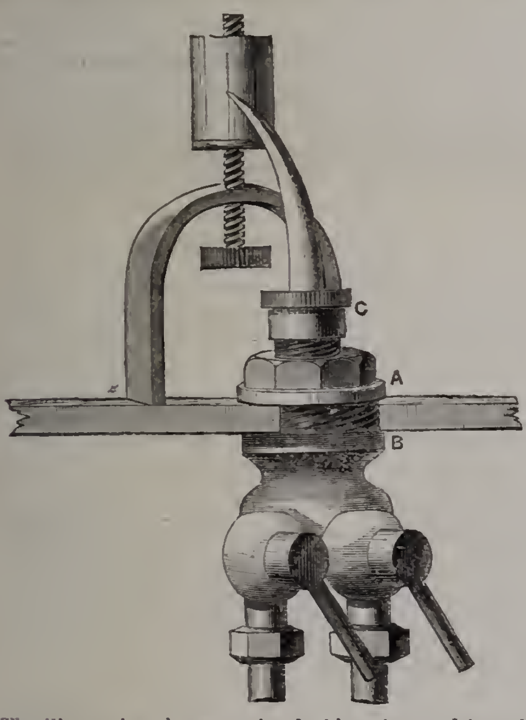
Process.—Hem! Upon my word I begin to think that I have been seeking "in process" what I wanted "in power," as Sir Martin Archer Shee, of the Royal Academy, said. I really am much obliged to you, Lovetruth.

Lovetruth.—Art exists in nature, and we have only to learn the art of seeing pictorially, to reproduce it in our paintings and our photographs. Excuse me, Process, if I am somewhat tedious in always talking *art* at you. There are *so* many to talk about these interminable *processes* and *lenses*, that I feel, while my remarks on such subjects can well be spared, that I am the more bound to speak upon that subject which is not only most needed, but of which I have a better understanding, simply because it is one which I have studied professionally, and been educated to know the importance of in years of practical labour and experience.

Dear Reader,—Will you allow Lovetruth's remarks to plead also for yours very sincerely, A. H. W.

THE LIME LIGHT.

As the applicability of the lime light to photographic purposes has excited considerable attention of late, we purpose, prior to entering into details of its photogenic power, to give, for the benefit of those who are unacquainted with its details, some idea of the necessary appliances for obtaining it.



The illustration shows a simple blowpipe and jet, when fixed in a vertical position upon a board, which also supports the standard upon which rests the ball of lime.

The blowpipe is held in its position by means of the nut A on the upper side of the board, and the shoulder B on the under side. The screwed tube upon which this nut works is filled with fine brass-wire gauze, punched round with a gun punch, and rammed into the tube like so many "wads." The jet fits upon the end of it with a socket and shoulder, and is rendered air-tight by a leather washer, the cap C, tightening them together.

The standard is of metal, and through the top of it works a screw with a milled head at the lower end, and a carrier for the lime ball, brazed about an inch and a half from the upper end. The ball of lime has a hole down its centre, through which the screw passes: in size it may equal an ordinary wine cork. The two stopcocks communicate with the respective gas bags, which must have upon them an equal and similar pressure of at least a hundred weight. Care must be taken that these weights are not removed from either bag whilst the gas is turned on, or the bag having the greater pressure upon it will by degrees force a portion of its contents into the bag having the lesser pressure, and thus the gases will mix; this must, for the sake of safety, be avoided.

To use the lime light allow a stream of lighted, hydrogen to play upon the lime for a few moments. The flame is first of a pale yellow, and afterwards a deep red, caused by the combustion of the metal calcium in the lime: the oxygen is now turned on, and regulated so as to produce the best result. If the combined gases are turned too suddenly upon the lime, before it has had time to be properly heated, it will crack or decrepitate.

The lime must be kept in a bottle when not required for use, as the moisture it would otherwise absorb from the atmosphere would speedily destroy it.

It will be found that if twice the pressure is placed upon the gas reservoirs, or if the aperture of the jet is twice the size, so that double the quantity of gas is consumed, the light emitted will be not *twice*, but nearly four times as powerful.

The relative quantities of the gases required to produce the best effect will be one part of oxygen to two parts of pure hydrogen; but if common (carburetted hydrogen) coal-gas is used instead of pure hydrogen, the consumption of both gases will be equal.

The oxygen is the most expensive of the two gases, as it costs, when made on a small scale by the amateur or experimentalist, about fourpence a cubic foot: pure hydrogen, twopence a foot; and coal-gas, about fourpence halfpenny for 100 cubic feet as obtained from the gas-works.

Notwithstanding the expense of oxygen, it has been proved that the lime light can be used so as to cost 25 per cent. less than coal-gas, and yet give ten times the light; this is owing to the small quantity of the combined gases required to render a certain amount of lime incandescent.

A method has recently been discovered of making oxygen at a merely nominal cost; but the price as above given is when chlorate of potash and black oxide of manganese are used.

In regulating the light, it is necessary to use dark spectacles to preserve the eye, which would otherwise be temporarily incapacitated either for focussing or manipulating in the dark-room.

The blowpipe is sometimes fixed in a horizontal position, and the jet is curved backwards in the direction of the stopcocks. The standard holding the lime will still retain its vertical position, but it must be placed so that the ball of lime shall be between the stopcocks and the aperture of the jet, from which it is distant about one eighth of an inch. This position is often adopted for the lantern for dissolvgin views.

Scientific Gossip.

There is perhaps no substance employed by the photographer which is more systematically adulterated than the chloride of gold used for toning purposes; the great intrinsic value of this article offering a strong inducement to dishonest traders to add to it some other chemical of comparatively little value, with the object of increasing its bulk and weight. If the advantage so derived be great to the adulterator, the evil is not less to his victim, and we think it right here to draw attention to the results of some analyses of commercial chloride of gold which have recently been made by Mr. R. Reynolds, the full details of which will be found on another page.

It will be seen that in one sample the amount of fraudulent sophistication was in all 31·7 per cent., or an excessive profit of £31 14s., or in other words a barefaced robbery of the above amount, on every £100 worth sold.

Mr. Reynolds considers that the deliquescent nature of the pure chloride of gold renders it a difficult matter to fill the bottles with accuracy as to weight, whilst the varying amounts of moisture which the maker may leave in the salt will always be a source of discrepancies in value. He suggests that the former difficulty may be overcome by sending out the solution instead of the solid choride. At the least, purchasers should require a guarantee of seven grains of pure gold in each bottle professing to contain 15 grains of of the chloride, whether the contents may be solid or in solution. A still better plan, in our opinion, would be to adopt the plan which we have before advocated in this journal, and replace the chloride of gold by the sodiochloride. This answers in all respects as well as the chloride, whilst it is easily obtained pure, and being non-deliquescent, there would be no reason why the purchaser should not have the exact number of grains he requires weighed out to him from the stock bottle, just as he does any other chemical. One difficulty, that of short weight, would thus be got rid of, whilst the remaining one, that of adulteration, would soon disappear if the maker knew that his chloride of gold and sodium, plus an unlimited excess of chloride of sodium, would, in all probability, be submitted to analysis, and the results, with the maker's name attached, published the next week in the PHOTOGRAPHIC NEWS.

Some experiments rather important to photographers have been recently completed by a Mr. King, on the amount of light which is absorbed by glass of different kinds. The results obtained are very interesting, more especially as it is a subject which directly affects those who are in the habit of working in glass rooms, and has not hitherto attracted the notice which it deserves. The following are the percentages of light which was found to be lost by the use of different kinds of glass :—Clear glass obstructed 10·57 per cent.; ground glass, 29·48 per cent.; smooth opal, 52·83 per cent., and ground opal 55·85 per cent. As the large amount of light lost by the use of a clear glass shade excited some surprise, a sheet of common window-glass was placed between the burner and the photometer screen, when it was found that 9·34 per cent. of the light was intercepted, thus confirming the result obtained by the employment of a shade of clear glass. These experiments show what care should be taken in the selection of the most colourless and clearest samples of glass for glazing the operating room; for even when perfectly clean, it will seen by the above that no inconsiderable portion of light will be obstructed by the glass, whilst if dirty, the atmospheric action must be enormously increased when it is seen that even clean ground glass will cut off nearly 30 per cent. of the actinic rays. It should be mentioned, in passing, that Verver has previously called attention to this subject. In 1858 he wrote, "It is not necessary to surround the wick (of platinum placed in the flame of 'water gas') with glass chimneys, as with ordinary coal gas; on the contrary, it is preferable not to employ them, because the chimneys, no matter how well polished, or how clean they may be, always absorb a considerable portion of the light which is produced. This loss is shown by the following experiment:—A burner with twelve jets without any chimney, afforded an illuminating power of 6·75 candles; but on surrounding the wick with a clean and perfectly polished chimney, the illuminating power amounted only to 5·25 candles; it had consequently diminished 1.50 candles, equal to 22 per cent." These experiments of Vevers are likewise important, now that artificial light is being employed for photographic purposes; they show the great importance of having the illuminating rays as free as possible from any obstruction of shades chimneys, lanterns, &c.

An enterprising American firm, the Waterbury Cotton Company, have been making a good thing out of the recent election of president. They are the proprietors of a patent by Mr. D. F. Maltby, for the manufacture of a small medal, composed of a ring or plate of solid metal, constituting a frame of a metallic character, surrounding a photographic portrait. The owners of the patent hit upon the idea of issuing photographic medals of the different presidential candidates, and the idea taking with their supporters, an enormous demand sprang up for these party emblems. At one time the firm were turning out upwards of 20,000 medals a day.

A patent has been recently taken out by Mr. W. P. Shaw, of Bunhill Row, for the application of the principle of the stereoscope to the instruments known as "Thaumatropes" and "Phenakistoscopes." These, as is well known, give to objects shown by them, an appearance of motion. By these improvements, the patentee causes the objects to appear also in solid relief, as when seen in the ordinary stereoscope. He takes from a suitable object a number of photographic pictures, the pictures being taken in pairs, having a stereoscopic relation the one to the other. Between the taking of each pair of pictures the object is caused to perform a portion of the movement which it is desired to represent, the first pair of pictures being taken at the commencing part of the movement, and each successive pair showing the same somewhat further progressed than the previous pair, until the last pair shows the object at a point just before it regains its first position. Having obtained these pictures, he views them by means of a stereoscope, and by suitable mechanism, causes the pairs of pictures to be changed rapidly, each pair being submitted to the eyes in succession for a moment of time. When thus seen, an appearance is obtained as of a solid body in motion. Mr. Shaw is late in the field. Besides the suggestion (and we believe realisation) of such a machine by Mr. Claudet many years ago, Sir John Herschel proposed the very same plan nearly a year ago in these pages, and since then it has formed the subject of one if not more patents before the present one was taken out.

Notes and Jottings.

No. III.

PRINTING IN SKIES FROM "STOCK NEGATIVES."—ON HANGING PICTURES DISTORTED FROM "COCKING" THE CAMERA.

IN discussing Mr. Fry's paper on "Instantaneous Photography," at the meeting of the South London Photographic Society, on the 20th ult., Mr. Hughes took exception to the plan of printing-in skies from stock negatives, remarking that "no sky will ever harmonise like the one that existed when the view was taken." We cannot entirely concur with Mr. Hughes on this point, although cordially coinciding with many of the ideas he at the same time so eloquently expressed.

It must be borne in mind that the clouds which almost entirely influence light and shade, are those situated between the sun and the landscape,—I am speaking of ordinary cases,—in which direction the photographer is not habitually fond of pointing his camera.

Let us suppose ourselves about to photograph a view on a "painter's day," with the sun on our right or left. It may possibly happen that at the moment the shadows of the flying clouds produce some wished-for effect on the landscape, we get nothing but blue sky for the camera, or, probably, clouds just where they are not required. We may *by chance* obtain the necessary balance of light and shade, but the contrary is far more likely.

An artist arranges the sky so as to harmonise with, and balance the other portions of his composition; and if, in photographing, he waits for the clouds to be as he would wish, in all likelihood the desired effect in the landscape is lost. Under these circumstances his only way is to take each at a different time and combine them.

In photographing a certain class of views, such as, for instance, when the camera is pointed directly towards the sun, it will be extremely difficult, and often impossible, to get any sky to harmonise as well as the one that existed at the time. But the best general effects are obtained with a side light, and not when the sun is directly behind or facing you. In all but the last-named instance, as before stated, the clouds got by the camera produce no effect on the landscape otherwise than by reflecting light, which, compared with direct light, is of little weight,—and thus the photographer, if he desires a composition according to rule, is necessitated to adopt the plan advocated by Mr. Fry.

We may possibly have read Mr. Hughes too literally, and he perhaps only deprecates the employment of such means by those who have not the requisite artistic knowledge. If so, he is undoubtedly right, for a well manipulated "rule of thumb" photograph in such a person's hands would chance to have the good qualities it happens to possess, spoilt. Nevertheless, that is no reason why others more experienced in the rules of art should not endeavour to produce a higher order of artistic pictures, by some method similar to that advocated.

Should you chance to possess a photograph having converging perpendiculars, produced by "cocking" the camera, viewing it in an inclined position, the upper part being nearer the eye, the distortions can be made to disappear.

It is customary in hanging a picture above the level of the eye to cause it to slant off from the wall more or less, to an extent depending on the height at which it is placed, and the distance from which it is to be viewed. The rule is, that a line drawn from the spectator's eye should fall perpendicularly on the plane of the picture. It will, therefore, readily be seen that by inclining your photograph beyond this, the distortion may be considerably lessened in appearance. MICHAEL HANNAFORD.

LUNAR PHOTOGRAPHY.

BY SAMUEL FRY.*

PHOTOGRAPHY, as generally understood, seems so inseparably connected with the light of day, that it appears at first glance anomalous to speak of taking pictures at night without artificial light; but one moment's consideration points to the true state of the case; though to us it be "dark as Erebus," to the lunarians, if such there be, inhabiting that portion of the moon's surface which is turned towards us, it may be broad sunshine, sunrise, or sunset, according to the moon's age and position. If, therefore, we choose a time for our operations in which we are favoured by the same atmospheric conditions required for producing good terrestrial pictures, we have many probabilities in our favour of obtaining good photographs of the moon. It has been matter of surprise with many that lunar negatives display a much larger variety of tone, and gradation of shading than the eye can detect on the surface with a telescope, but photographers will easily understand that this is of necessity the case, as whilst large tracts of the moon's surface north-west of Tycho, and also south of that centre, are of a silvery whiteness, other parts to the east and south-east of the lunar surface, present varying hues of yellow and green, each shade having its actinic value, and being accurately impressed on the photographic medium. And this variation in colour is a very happy circumstance for us, as, if the pure silvery tone of the upper portion extended over the entire disc, how flat and chalky would the pictures be.

The darker portions of the moon's surface are generally known as seas, but the appellation appears to be a gratuitous one, as beyond the supposition which some have entertained that the colours before alluded to were caused by sands and other deposits, constituting dry oceanic beds, there appears no other cause for thus denominating what are evidently now dry arid tracts.

My attention was first called to the photography of the moon at the commencement of 1857, by having placed at my disposal the very fine equatorial telescope of Charles Howell, Esq., at Brighton, which had then just been erected in a suitable observatory on the beach, about a mile from the town. I determined to commence operations at once, and with that object fitted up a little laboratory in another room of the observatory, adjoining the instrument room. I found a difficulty at starting arising from the circumstance of the extreme cold of the place, greatly reducing the photographic power of the chemicals, and it was thenceforth needful to keep the bath and developer in a dwelling-house for warmth. I then commenced experimenting for the purpose of discovering the exact actinic focus of the telescope, for as the object glass of 8½ inches diameter, and 11 feet focus was not corrected for the chemical rays, it was necessary at starting to discover the point of sharpest possible focus. I had made a mahogany board, 12 inches long and 4 wide, with a screw extending the entire length, and so arranged, that by turning a thumb screw at one end, an upright plate-holder at right angles with the board could be moved in either direction. I also made a graduated scale of degrees along the board divided into $\frac{1}{100}$ of an inch; the eye piece of the instrument being removed, this simple camera was by means of an adjusting collar fastened to the end of the telescope, by the thumb-screw at the end. I obtained a remarkably sharp image at the visual focus, about 3½ inches from the aperture of the telescope, and I began by taking a picture at this point, which, of course, from the non-correction was quite out of focus, but was preserved for comparison; I then began by removing the prepared plate $\frac{1}{10}$ of an inch back from the visual focus, and soon found my pictures showed evidence that I was approaching the true focus. I ultimately found that the average sharpest focus was at 0·75 inches beyond the visual, but I found constantly a slight, as it were, oscillation of focus within, and beyond this point, caused primarily, no doubt, by the varying distance of the moon from the earth, and also to a certain extent by the condition of our atmosphere. M. Claudet was one evening with me at the observatory, and stated on being informed of this circumstance, that he considered it a striking corroboration of a theory he had advanced at an earlier stage of photography. I always found it necessary on commencing operations to make one or more trial pictures, to discover the very sharpest possible focus, and on more than one occasion, when the moon was in a plane peculiarly suited for delineation, great loss of time arose from overclouding, and other unfavourable conditions of atmosphere. For this reason a reflecting telescope is greatly to be preferred to a refractor, as by a reflector the focus may be obtained as in an ordinary camera from the coincidence of the foci.

I now come to the mechanical arrangement necessary for driving the telescope to follow the moon's apparent path, For as even under the most advantageous circumstances an exposure of a few seconds is necessary to secure a good negative, it is indispensable to annul the rapid lunar motion by most accurate smooth running machinery. This was done by a powerful clockwork, regulated, as Mr. De la Rue describes his also to be, by a conical double beat pendulum, acting on the same principle as the governor of a steam engine. This was easily set to go at any given speed by a dial, and degrees marked thereon, and a few experiments enabled me to set it at any given time to exactly follow the moon; though at first it was rather difficult to discover whether want of sharpness arose from incorrectness of focal position, or want of adjustment of the clock-movement, the mistiness being much the same from each, but the latter fault gives also a rather oblong appearance to the image. With regard to the chemical part of my arrangements, I find it of primary importance to employ the very best chemicals, and the highest possible state of cleanliness; perfect freedom from floating particles in the bath, collodion, or developer, and all three so suited to one another, as to work uniformly together. I prefer positive collodion, as being more limpid, and thus pouring better, also from its usually containing both an iodide and bromide, in its composition; it does not deteriorate in sensitiveness to any extent, which enables one to keep it in a body in tall bottles and allow every particle to settle down to the bottom, and thus draw from the upper portion a quantity absolutely free from all inclination to produce spots, or comets. The bath I prefer of 40 grains to the oz., made of pure crystals; and if at

* Read at the meeting of The London Photographic Society, on Tuesday, Jan. 8, 1861.

all acid, I reduce it by saturation with the oxide of silver, and add, testing carefully meanwhile, drop by drop, a weak solution of nitric acid.

I believe this is the way to obtain a bath capable of producing the very highest results for any branch of photography. The developers I use are sometimes pyrogallic, 3 grains to the oz., and at other times iron of 10 grains, and 1 grain of acetate of soda. Under very favourable circumstances I use the former, as giving at one operation a vigorous well-defined negative, but where I have to contend with yellowness of the atmosphere and its concomitant photogenic drawbacks, I use the iron solution and intensify afterwards with pyrogallic and citric acid. In using iron it is absolutely necessary to hit upon exactly the right time of exposure, as a second too much or too little I find sufficient to mar the picture to a much greater extent than when pyrogallic is used. The extreme difficulty of obtaining good lunar negatives would scarcely be credited without actual experiment; the disturbing causes are so numerous, and apparently so trivial, and yet, so often fatal; a strong breeze in the upper regions of the atmosphere when almost calm below; night vapours and mistiness arising after a warm sunny-day; or, when all the preparations are made, and the photographer at his post, perhaps at midnight, or often much later, cloudiness may set in, and completely upset every chance of getting pictures. In so variable a climate as ours, the opportunities of obtaining really fine lunar negatives are like "angels' visits, few and far between."

Correspondence.

LONDON PHOTOGRAPHIC SOCIETY.

"The object of the Photographic Society is the promotion of the Art and Science of photography, by the interchange of thought and experience among photographers."—Vide *Journal of the Photographic Society, opening statement of Volume I.*

SIR,—I am a member of the above society, and feel a keen interest in its behalf. Yet I am not satisfied with its proceedings, and your journal being the organ of no society, I feel in addressing my remarks to you I am treading on neutral ground. I feel that our society does not get on in the same ratio as some others, and this arises, I think, from its very constitution. This may have answered in the commencement, but I do not think it suited to it now. Three years ago it was proposed to revise our laws, and two years since, at the annual meeting, the Lord Chief Baron said, "the laws, although adapted to an embryo state, were undoubtedly liable to objection, and we were promised that the Council would consider the matter and amend the laws;" and yet to this day they are not amended, and there is no probability they ever will be unless there be a pressure from without. Nay, what these laws are, very few know, for they have been two or three years out of print. This is not what it should be, and in part is owing, I think, to the cumbrous machinery of our government. Our affairs are managed by a president, three vice-presidents, a secretary, a treasurer, and nineteen members of council, one-third of whom retire annually, and as the new members are nominated by those remaining, for all practical purposes this council may be said to be self-elected.

"The object of the Photographic Society is the promotion of the art and science of photography, by the interchange of thought and experience among photographers;" these are the opening words of our journal, and one naturally expects that those who are placed on the council are the members best able able to further this object, Let us see who the council recommend next annual meeting to be elected:—The Earl of Caithness; Mr. Warren De La Rue, F.R.S.; Mr. Walter Hawkins, F.S.A.; Rev. J. B. Major: Mr. T. R. Williams. Now, these gentlemen may be the very best that could be selected "to promote the art and science by the interchange of thought and sentiment," during the next three years; but I should like to know what principle governs their selection.

The Earl of Caithness is, I doubt not, a highly intelligent nobleman, and if he has acquired a knowledge of our art, I shall be glad to hear of it; but I know of no reason whatever why he should be entrusted with the management of our society, and for that reason, with all due respect, I shall decline to vote for him.

Mr. Warren De La Rue is a highly distinguished man of science, and well known in connection with celestial photography; and our society will be honoured by having him for one of its councillors, more particularly if he will come amongst us, and give us the benefit of his photographic experience, and of which we can have no doubt, from the kindly and deeply-interesting communication he gave at the last meeting.

Mr. Walter Hawkins is, I believe, quite unknown to us, and why he should be recommended to me to "promote the art and science" I cannot tell; but I shall erase his name, and put in one that I have confidence in.

The Rev. J. B. Major was for a time our secretary, and although he acquitted himself in a desirable manner, I never heard that the society benefited by his management, or that he in any other way has earned the position of a member of council.

Mr. T. R. Williams: this getleman we do know, as being one of our cleverest portraitists. Gentlemen distinguished for chemical photography, landscape photography, and no photography at all, have had seats at the council; but this is the first time an avowed professional has been offered one. I congratulate the council on their tardy justice to the most universal branch of the art. Hitherto it has been considered that a gentlemen might derive any amount of pecuniary gain from the art, and yet keep a seat at the council; but that if he publicly adopted it as a profession, he would be disqualified. I am glad this invidious distinction has been removed, and that while the doors of the council chamber are open to an unknown Earl, they are also ready to admit a skilful portrait-taker.

But when this innovation was decided on, I cannot understand why this particular artist was selected. Perhaps I am hard to please, but I must return to my text, that the object of the society is "the promotion of the art and science by the interchange of thought and experience," and seeing this gentleman has never yet interchanged his thought and experience with us, nor even taken part in any of the desultory discussions, I cannot see why, highly skilful and meritorious though he be, he should be selected in preference to others who have contributed.

Professor Bell, I find, is to go up to the vice-presidency, and Mr. Fenton to descend to the council-board, and by this interesting change of seats the art and science of photography will doubtless be materially "promoted" during the ensuing year.

Now, seriously and earnestly, I ask, is this the way to manage what ought to be the best society in the kingdom? Many times last season we had most dreary meetings, and once or twice literally nothing provided. On the first night of this season, after a vacation of many months, only parts of a dry mathematical paper, without diagrams, were read, at the next meeting we were instructed how to protect our negatives with an antiquated and exploded varnish, and at the very last meeting neither president, vice-president, or one of the nineteen councillors were present even to take the chair.

Such a society as ours ought to be the best managed in the kingdom—should have a plethora of papers, and not a meeting should pass without some valuable or at least useful contribution being made. To read a paper before such a society ought to be held an honour, and only worthy matter be introduced. No society can be compared with ours for the advantages it possesses. It is the oldest, the largest, and the parent of all others. It is patronised by royalty, graced by nobility, and made illustrious by distinguished members. It established the first journal exclusively devoted to our art, and by its successive annual exhibitions gave that impetus to photography that has made it what it is. And shall a society like this die out, when small provincial and suburban ones are full of life? Nothing is wanting but skill and energy to make this society greater than ever it was. No other society has a paid officer, and his business it should be to put himself into communication with everybody and everything bearing on the art, so that information might stream in from all quarters.

Our society, with its clumsy machinery, is too much like the Lord Mayor's state coach—heavy, lumbering, and fit only to go at a slow pace; but these are not slow times. Photography is the type of the age, it won't wait. Go on we must, or we shall be run over by those behind, and it is for my fellow-members to bestir themselves to prevent our society being extinguished by the apathy of our executive, or the superior energy of rival societies.

Hoping that these remarks will rouse attention to the important subject I have broached, I subscribe myself,

Progress.

WHO DISCOVERED THE COLLODION PROCESS?

Sir,—I would, with your permission, call attention to a communication read at the last meeting of the French Photographic Society, regarding the place Scott Archer, and in fact England, should occupy regarding the introduction of collodion as a photographic material. I am the more disposed to do so, from observing that M. Lacan, who was present at the meeting, has not noticed the article at all in his letter to a contemporary, though in it he expresses his regret at the poverty of photographic news.*

The communication referred to was made at the meeting of the *Societé Française de Photographie*, held on the 23rd of November, and is reported in the society's organ for December. It is described as a "Historical Note on the Labours of Le Gray in the employment of Collodion;" but the real purpose of it is more distinctly set forth in the preamble, which states that in the following note M. Humbert de Molard purposes to demonstrate, by extracts from original publications, that M. Le Gray was the *first* to recommend the use of collodion in photography, and that he had anticipated the discovery of Mr. Archer.

Now, I think this a rather important matter, and would gladly, if my time permitted, give the Frenchman's edition of the early history of the collodion process *in extenso*, with the important omissions he has made filled up, and if no one is more competent to take the subject up, I may at a future time do so more at length. Meantime, I wish to call attention to the article, that British photographers may know what is the opinion of the Photographic Society of France; but more particularly to notice a very grave error M. Humbert de Molard has fallen into, in his so-called extracts from original publications. He says, 1851, 20th of November, "*Athenæum*, *first communication* of Mr. Scott Archer." I had always supposed that Mr. Scott Archer published his all-important discovery in the *Chemist* for March, 1851.† Without entering on the main question, whether Mr. Scott Archer was really the first to give a photographic process with collodion, this is a very grave blunder in a communication which aims at historical accuracy, read to a scientific society, and published in the society's Transactions, with the seal of their approbation.

The readers of the Photographic News are no doubt aware that Mr. J. E. Tunny of Edinburgh has some time ago announced that he began to work with collodion from the information obtained through the publication of Le Gray, said by M. Humbert de Molard to have been published in June, 1850. The satisfactory verification of these two facts is the whole question. Did Le Gray publish directions for taking pictures by collodion on glass in June, 1850, and did one or more persons, actually following out these instructions, take pictures? The exact date of Mr. Archer's publication is easily ascertained, as he published in a periodical publication whose date is known with certainty. Le Gray's presumed prior publication—which, observe, I do not for one moment either, in present circumstances, doubt or deny—is made in an appendix to a treatise on the art in general. The date of the publication of this appendix is not so easily or certainly ascertainable as that of a magazine appearing regularly.

I need not say I have no wish to set up one over another as the true inventor of this process, my aim is to ascertain with an approach to certainty what is the truth, and if my brief note call attention to the pretensions of our Gallic neighbours, it will serve the purpose I have in view. Honour to whom honour is due, is a maxim, and I am sure British photographers do not desire any exception in this or any other case. Le Gray is already honoured amongst us, as a most prolific photographic inventor, and one of the most successful operators in our fascinating art, and no one will grudge him a higher place if it is proved to be his due, and, if I am not mistaken, least of all would the talented artist we are accustomed to recognise as the true discoverer of the photographic capabilities of collodion have been disposed to do so, had he been still with us.—Yours, &c.,

Glasgow, Jan. 2, 1861. John Cramb.

* The subject is noticed by our Paris Correspondent in last week's Photographic News.—Ed.

† Mr. Scott Archer's communication is dated 18th of February, 1851, and appeared in the March number of the *Chemist.*

FOREIGN SCIENCE.

[from our special correspondent.]

Paris, 9th January, 1861.

Photographers have reaped a rich harvest in Paris during this festive season, for among the *élite* the choicest gifts and the most acceptable presents on the *Jour d'An* have been photographic gems. Not such things as you see in every shop window, and can buy for five francs, not at all; but real gems that have never before been photographed, such as every amateur, connoisseur, and dilettante would delight to add to his "Harvey" portfolio. Now it is a copy of a Carlo Dolce or a Gerard Dow, or an *Immaculate Conception* of Murillo; a chiselling of Benvenuto Cellini's or of Pradier's; or it is a *fac-simile* of a page of a rare missal or illuminated manuscript—anything, in fact, particularly *recherché* or unique. Favoured fair ones show their albums exultingly, half-filled as they are with such photographic treasures as I have specified. As these are for the most part the works of cultivated amateurs, of course they are the more highly prized, inasmuch as they have not the odour of the *boutique* about them. The array of *cartes des visite* which some fashionables have received from their guests is truly marvellous, alike for the personal interest of the portraits, as well as for the extent of the collection; and it is in the production of this class of photographs that the industry of professional photographers has been exercised so extensively.

In a recent letter I described M. Fargier's process of carbon printing. As it was not quite successful in the hands of certain amateurs who tried it, the inventor has kindly furnished minute details, which I think will tend to remove any difficulty that may be encountered in repeating his experiments.

M. Fargier first points out a radical defect in the processes employed previously to his own, by M. Poitevin and others, viz., the carbon mixed with gelatine, &c., is not a solution, but a powder held in *suspension*, which has never sufficient tenuity to penetrate the pores or even into the substance of the paper, and consequently it remains on the surface of the paper, and forms with the gum a coating of a certain thickness. Now, however thin this coating may be, the light does not act at once throughout its entire substance. The light acts in proportion to its intensity, this intensity is greatest at the surface of the coating, and gradually diminishes as it penetrates the thickness of the coating; therefore the coagulation of the coating must commence *at the surface*, and is continued further and further into the interior in proportion as the exposure to light is prolonged. From this fact it follows that the picture formed on the gum spread upon paper, as above mentioned, is not directly sustained by the paper, but rather by the gum which the light has not penetrated, and which, consequently, remains soluble. It may readily be imagined that the picture will disappear when it is washed in water, at least, the half-tones will, and they are the most essential to a good picture; for the deep blacks, which the light has passed through and through, rest directly in contact with the paper, and remain.

But if, after having prepared the sheet of paper as above directed, the negative is placed, not on the prepared gelatine side, but on the back, so that the light which passes through the negative traverses the paper before it reaches the gum, coagulation will then begin at the surface of the gelatine *in contact* with the paper, and the *whole* picture will remain on the paper after washing. It was in this manner M. Fargier obtained his first proofs, but it has some inconveniences; the time of exposure is necessarily longer, the proofs are reversed in position, and they have a granulated appearance, arising from the light passing *through* the paper, and this is not uniformly translucent.

Since then, M. Fargier has substituted collodion for the paper, with complete success.

In some experiments recently conducted with a view of ascertaining how much light is intercepted by different kinds of glass, it was found that "English plate," one-third of an inch in thickness, intercepted 6·15 per cent, of light; "crystal plate," one-eighth of an inch thick, 8·61 per cent.; "English crown," of the same thickness, 13·08 per cent. This great loss of light may be partly accounted for by the conversion of a portion of the light into heat—an effect perfectly in harmony with the theory of transverse vibrations, as applied to explain the phenomena of polarization of heat. On this theory, heat and light are different effects produced by one and the same cause, and they differ physically only in the amplitude and rapidity of their vibrations. The screen through which the vibrations of light are propagated serves to diminish first the rapidity of the vibrations requisite to produce the most refrangible rays, and in proportion as the transparency of the screen is diminished by any cause, inherent or superficial, this arrestation becomes more and more complete. As the more rapid ethereal vibrations have probably the least amplitude, we infer from analogy in sound-waves, that as waves of least intensity have the greatest amplitude, so with the luminiferous ether the extreme red has but little brilliancy. Hence the loss of light from polished screens is small compared with that observed in screens of opaline or roughened glass. It would be instructive to examine the spectrum obtained from a pencil of rays under each of the cases given in the above experiments, by means of a sulphide of carbon prism.

In connection with this subject it may not be inappropriate to refer to the experiment of Dr. Draper, on the spectrum formed by means of a platinum wire, heated gradually from dull redness to perfect whiteness by a voltaic current. He observed the red part of the spectrum to appear first, and as the heat and luminousness of the wire increased the other colours of the spectrum appeared after the violet. This result perfectly harmonises with the views expressed above.

Beyond this, there is little photographic progress to record. The weather is too cold for operating; so we are busying ourselves in putting our houses in order, and preparing for next season's campaign.

PHOTOGRAPHY IN GERMANY.

Elberfeld, December 28th, 1860.

Having lately received a lot of Dr. Hill Norris's dry plates, I proceeded to make some experiments, for rapid results, with them. I exposed a quarter plate, with a German 1½-inch portrait-lens, 15 seconds in the glass room, moistened the plate with distilled water, poured some 5 per cent. nitrate of silver solution upon it, and developed by protosulphate of iron, (5 per cent. of this salt, and 7 per cent. of acetic acid). The picture came out very clean and fine, but too transparent. In order to strengthen it, I added to the iron solution a few drops of silver solution, poured this on the picture, and so I got a remarkably fine negative. Having fixed with hypo, I let the plate dry before a fire; but in drying, the upper part of the collodion film contracted, and several transparent marks appeared and spoiled the picture. Of course, this resulted from a too dense precipitate upon the film. I tried therefore, only to make the image darker, without employing much silver. Having exposed a second plate, with a single landscape-lens, and small stop, (it was a cloudy day, but the ground and houses were coated with snow,) 10 seconds, I developed as before by sulphate of iron, then washed, and strenthened as usual, by pyrogallic (and citric) acid, and nitrate of silver. An excellent negative was the result, dense enough in the lights, and very transparent, and detailed in the shadows. The colour was of a greenish black, similar to the colour of a negative upon collodionized paper, which copied very rapidly. The collodion seems to contain much water, too much at least for my taste. I think the plates may be recommended as giving safe results.

Here I may note that some years ago I got equal results upon dry collodion plates, prepared by M. Quinet, of Paris. I do not remember to have met with one failure. The collodion film was more solid than Dr. Norris's, and it was impossible to remove it by washing. The plates were developed by two solutions delivered by the inventor, and consisting, I believe, the one of a mixture of pyrogallic and gallic acids, and the other of silver solution; but I got the same results in using pyrogallic acid. The last of these plates was exposed fourteen months after the preparation, it was as sensitive and good as the first ones. The collodion sold by M. Quinet for preparing these plates was very thin, contained a large excess of ether, and remained of a light yellow colour. With the collodion I never got as fine results as with the ready prepared plates. I think the collodion contained resin.

Herr Schrank, of Vienna, states in a correspondence to the *Photographisches Archiv*, that he has found a means to produce thin and transparent negatives, which copy in half the usual time, but are strong enough to give good contrasts. He describes his process in the following terms:—

Prepare a bath of acetate of silver, concentrated, because this salt is not very soluble in distilled water. Having excited a collodionized plate in a neutral nitrate of silver bath, drain off the solution, and put the plate for some seconds into the second bath of acetate of silver. (This bath is to be kept in the dark, because in the light it readily decomposes, from its organic character.) Expose and develope as usual by the pyrogallic. The negative comes out in an orange-yellow colour, which turns into an agreeable bluish violet, when nitrate of silver is added to the developer. It is important to remark that this proceeding *allows the time of exposure to be shortened one-half.*

At Vienna, a "Society for the Advancement and Development of Photography" has been formed, under the presidency of M. Schrötter, a well-known chemist, and Pezval, the calculator of the portrait and orthoscopic lenses.

Dr. Schnauss, entering into the subject of several remarks made by Mr. Sutton, about the formation of acetate and oxalate of silver in the silver bath, believes that these combinations will not exist in the bath if they are not added directly to it. He reminds the reader, that during the transformation of the ethyl order—to which alcohol ($C_4H_5O + HO$) and ether (CC_4H_5O) belong—to the acetyl order (C_4H_3) *before* the formation of acetic acid ($C_4H_3O_3 + HO$) there is yet a grade between, viz., the aldehyde ($C_7H_3O + HO$). This perhaps could be present in the bath. He believes that several salts of ether, acetic ether, and perhaps also nitric ether, can be formed; and he sometimes found the first one in old baths. The acetic ether dissolves pyroxyline, and in that manner small portions of this may pass into the bath. Acetate of silver can only be formed when acetic acid and a free alkaline carbonate be added to the bath, or an acetate. Acetic acid alone cannot separate the strong nitric acid from the oxide of silver. By the use of an alkaline collodion, acetate of silver perhaps could be formed.

Now, coming to the formation of oxalate of silver, we must ask, whence the oxalic acid may come? It is formed by the influence of nitric acid upon the carbo-hydrates (?) (kohlenhydrate), for example, the sugar and the cellulose. It is evident that it may be formed during the preparation of pyroxyline, and thus go over to the collodion, being soluble in alcohol. It should be purposely tried, in what manner oxalic acid acts when introduced into the collodion. Probably in the same manner as acetic acid.

Well, suppose the collodion to contain oxalic acid, may it be in a free or bound state? Let us see how it reacts upon nitrate of silver, in order that we can estimate of its effect upon the bath.

A solution of oxalic acid, poured into a 40-grain solution of nitrate of silver, produces a thick white precipitate, which is insoluble in water, but soluble in strong acids. By the precipitation some nitric acid gets free, and a small portion of the oxalate of silver remains in solution, so that the filtered part is troubled [rendered turbid] by chloride of sodium. But in adding an oxalate (oxalate of ammonia) to the silver solution by double decomposition, nitrate of ammonia and oxalate of silver are formed. By this way the silver can be completely precipitated out of a neutral solution, so that chloride of sodium does not longer render the filtered part turbid. Only when much nitric acid is present in the bath—and this never *should* be—a trace of oxalate of silver would be dissolved. Of course, it could be formed in the collodion film itself, beneath the iodide of silver, when the collodion contains oxalic acid or an oxalate.

Surely, there is yet to dig out a hidden treasure concerning the salts of silver in photography.

The *Photographischer Almanach für das Jahr* 1861 is a small luxurious printed book, issued at Berlin. Besides a record of the progress of photography, it contains several humorous stories and poems about photographic occurrences. The title-page is decorated by a beautiful photograph.

The addition of an acetate to the negative developer is certainly an old thing, as "An Amateur" (PHOTOGRAPHIC NEWS, p. 382) remarks, and was first recommended, I think, by M. Gaudin. It would be a rather difficult task to think only about *new* things, when we remember the old saying, *Nil novi sub sol.* The stereoscope may have been known some two hundred years ago. The industrious American made, a few years ago, an invention to photograph without a lens, using a dark box with a hole, the same instrument first used by Porto, the inventor of the camera-obscura. Mr. Griffith has now detected the iodo-nitrate of silver, though Dr. Schnauss made known the formula of this combination in *Dingler's Polytechnisches Journal* of 1855, likewise proposing to use this double salt directly in the collodion.

> Die Welt wird alt und wieder jung,
> Doch der Mensch hofft immer verbesserung!
>
> (The world gets old and again young,
> But men hope always for improvement!)

A similar case occurs with the employment of electric light to photographic purposes. The first experiments in this direction were made by Schroeder and Schaufuss, of Leipsic, 1858.* A Bunsen-battery of forty-one elements was used, and a negative got after a photographic picture in two minutes. In ten minutes a feeble copy in the pressure frame was obtained.

I may remark here, that in the cloudy, snowy days before Christmas, I have regularly made use of the electrical light to accomplish a very considerable number of copies. The cost I do not find too great. In short, I shall publish something more about this very interesting adaptation.

P. E. LIESSEGANG.

* We believe collodion pictures by the electric light were produced in Dublin at a date anterior to this.—ED.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF LONDON.

THE usual monthly meeting was held on the evening of the 8th inst., J. G. CRACE, Esq., in the chair.

The minutes of the previous meeting having been read and confirmed, the Chairman announced that the council proposed Mr. Vernon Heath and M. Joubert as auditors of the accounts for the coming annual.

Messrs. A. Claudet, Thomas Gillis, and Captain Verschoyle were elected as members of the society in the course of the evening.

A letter was read from Mr. Leighton, referring to an engraving, the designs of which had been photographed on wood from a negative of Flaxman's *basso-relievo*, and was published in the recently issued "Lyra Germanica." The letter referred to the difficulties which had been found in getting a photographic image on wood suitable for the engraver, and described the conditions required, but made no allusion to the method by which the engravings in question had been effected.

A very fine specimen of Mr. Osborne's photo-lithographic process was shown, consisting of a map of Cork. It had been forwarded from Melbourne to Mr. Hardwich by Mr. Osborne.

A plate-warmer, consisting of two flat boxes of tin, hinged together, which were to be filled with hot water, was exhibited by Mr. GUTCH.

Mr. DALLMEYER exhibited a stereoscopic camera with a simple instantaneous shutter, a description of which will appear in our next.

Mr. WARREN DE LA RUE, referring to the interest and importance of photographing on the wood block, said it was desirable that in regard to such a discovery exact dates should be fixed, in order that merit might be properly awarded. He remembered that some time in September a photographic transfer on to wood of a design, very similar to the one before him, was shown to him by his esteemed friend M. Joubert.*

M. JOUBERT said Mr. Leighton had called upon him in August last and asked him if impressions by his phototype process could be printed on wood. He told him he thought it could, and Mr. Leighton sent him the negative of the design now exhibited, and the design on the block now before them was one of those he had printed.

Mr. BOHN said he was not aware before that M. Joubert had printed the designs. A complete history of the matter would shortly be issued in "Jackson's History of Wood Engraving."

After some further conversation on the subject, in which the late Mr. Archer's attempts to meet the case by transferring collodion films to wood was referred to,

M. JOUBERT said that two years ago he had printed some photographs on wood, which he had still by him. The method used was the permanent printing process, which he had termed the phototype. He might here take occasion to say, regarding that process, that it was not yet published, chiefly because it was not yet in a sufficiently perfect state to be accomplished satisfactorily by ordinary workmen, but required skill and delicacy in manipulation. When he had brought it to such a state of perfection as to be quite certain in the hands of common workmen, he would make the process known. (This announcement was received with much applause.)

Mr. MALONE thought it important in discussing subjects of this kind that proper recognition should be made of all applicable methods which had been proposed. Mr. Crookes was not present himself, and he thought it only right to make mention of the method he had suggested of meeting the necessary conditions of photographing on wood, for the engraver, by using oxalate of silver. He was very glad to hear the frank explanation from M. Joubert regarding his process of phototype, and he hoped they might look forward for it soon. Regarding photographs on wood of transfers in printing ink, nothing, he thought, could be better for the purpose than Fizeau's photo-

* We can confirm Mr. De la Rue's statement, M. Joubert having shown to us at his studio, the designs in question, in September,

graphic etchings on Daguerrean plates. They were exquisitely delicate and full of detail, and capable of giving a sufficient number of impressions for all transfer purposes. He now took the liberty of suggesting impressions from these etchings for the purpose of transferring to the wood block.

The Secretary then read a letter on the subject of "Varnishes," in which the writer expressed his approval of white-lac varnishes, and his dislike of copal, which always cracked.

A letter from Sir C. B. Phipps was also read, stating that as Her Majesty was in the country neither she nor the Prince would be able to take their usual view of the exhibition, but would do so sometime before it closed.

Mr. Vernon Heath said it had been arranged at the last meeting that he should have an opportunity of making a few remarks regarding Mr. Dallmeyer's triplet lens. He found in the journal of the 15th of November, a letter referring to certain prints produced by Mr. Dallmeyer's lens, and in the same number was an advertisement making certain assertions regarding the lens. He was desirous of some information which he thought would be important to all. He wished to know what was meant by the statement that it was "quicker acting" than the orthographic lens or the ordinary single combination. Was it intended that the triplet lens, size of picture and of combination being equal, would produce a picture in a shorter time than the single lens? He must confess his experiments had produced a different result. He wished—

The Chairman interposed that he had understood that Mr. Heath had some explanation to make which would not occupy two or three minutes. They had an important paper to read and discuss, and if they entered into other enquiries, which must necessarily provoke discussion, there would not be time to do the subject of the paper justice.

Mr. Heath was in the hands of the meeting. It was their duty to prevent misapprehension, and he thought it a fair subject for present discussion.

Mr. Dallmeyer said, in regard to the statement of Mr. Heath—

Mr. Heath:—It is not a statement, for it is not yet made.

Mr. Bohn said such a subject should not be brought forward without proper notice.

Mr. Heath would like the sense of the meeting as to whether he should proceed.

The Chairman suggested that any further explanation should be deferred to the next meeting.

Mr. Malone thought they would be in the same position then. He thought no promise of an opportunity of bringing forward such a subject ought ever to have been given to Mr. Heath. If they were single out every ambiguity in letters or advertisements there would be no end of such discussions. He thought if they gave opportunity for discussion of this kind between gentlemen it would do them no credit as a society.

Mr. Heath again rose; but the Chairman called on

Mr. Fry, who proceeded to read his paper on "Lunar Photography." (See page 17.) After which

Mr. Warren De La Rue said he had listened with much interest to Mr. Fry's paper, and was glad that he was pursuing with assiduity his labours in that direction. There could not be too many labourers in that direction. There could not be too many labourers in such a field. If they had a dozen observatories, all attended by as skilful photographers, the result would be beneficial to astronomical science. In regard to the method pursued, it was all a question for experience to decide which gave best results. In his own hands, he had found best results from using fused nitrate of silver for his bath. He thought it was most manageable and least liable to change. He had tried the plan of neutralizing, or rendering alkaline with oxide of silver, and adding sufficient dilute nitric acid to bring the bath into proper condition, but he had never got a bath to work so rapidly, or to give such constant results as with fused nitrate of silver. The bath so prepared would give one or two foggy pictures, and then all would go on right. In the next place, as to development, he had generally found the best results from the use of the aceto-pyrogallic solution. He had used citric acid with the pyrogallic: it gave strong, vigorous, pictures; but there was a lack of that delicate transparency so essential for the correct rendering of celestial photography. He also found it wise to over-expose a little, so that the whole picture, with all its detail, developed directly, so that he could cease to develope at any point, without pushing some parts too far in order to bring out details in others. The collodion he had used was the ordinary negative collodion of Hardwich and Thomas, and he preferred the cadmium iodizer, as preserving its properties for a long time: it was, as Mr. Fry had well stated, of the utmost importance to have everything always in good order and ready for operations, otherwise, a fine night might be lost from the chemicals not being in order. All collodions iodized with potassium he had discarded, from their perpetual change and the uncertainty it introduced. Then as regarded the telescope, Mr. Fry had been working under some disadvantages; he had been using an achromatic telescope, but not one corrected for the actinic rays. There would be therefore some slight absence of sharpness, not due to any fault of manipulation, but solely to the instrument, as besides the defining rays, there were others not quite brought to a focus, which would cause a little confusion and want of sharpness. The instrument should be one corrected especially for the purpose. As regarded the driving clock he was constantly at work with one, but the best machinery would fail at some time; the beautiful motion of the earth was difficult to overcome, and the clock was constantly requiring some alteration. If it were set right to-night it would require some alteration to-morrow. The stress which Mr. Fry had laid upon the necessity for extreme cleanliness was of the utmost importance, as the smallest speck of dust would often derange results. He would now show some specimens, but he would ask photographers to remember that they were magnified eighty times, and they could scarcely expect the same sharpness as would be seen in ordinary photographs. The photograph of a part of the moon's surface which he showed had been magnified four hundred times. The mode in which it was produced was by putting the original under a microscope, and drawing in the parts by the aid of the camera obscura, and then producing from that a photographic copy. (Some very fine photographs were then handed round for inspection.) Then as to the production of stereoscopic pictures of the moon, if two pictures were taken differing only in libration of longitude, a satisfactory stereoscopic effect would be produced, but if they differed in libration both longitude and latitude they would only we stereoscopic under certain conditions. (Mr. De la Rue then illustrated by diagrams on the blackboard the effects of libration, and the condititions necessary, full details of which will be found in his pamphlet on celestial photography.) He concluded by stating that at some future time, he hoped to be able to give them some of his experiences in solar photography; but as he took part in the great expedition to Spain in connection with the solar eclipse, he could not do so until the results had been published altogether by the Astronomer Royal.

Mr. Shadbolt, referring to the method practised by Mr. Fry of producing first an enlarged transparent positive, and from that an enlarged negative, asked if he had ever tried the plan of taking a reduced transparent positive first, and from that an enlarged negative. He thought that greater sharpness would result.

Neither Mr. Fry nor Mr. De la Rue had tried that method.

Mr. Fry said if no other advantage had arisen from his paper, it had elicited the interesting remarks of Mr. De la Rue, with which he had entirely concurred. Regarding Mr. Shadbolt's question, he had thought that he had tried every method of getting a satisfactory enlargement, but he certainly had not tried this method of reducing first, and although doubtless the suggestion, coming from Mr. Shadbolt had weight, he did not see how superior sharpness would be the result.

Mr. De la Rue wished to add a remark touching the varying focus to which Mr. Fry had referred, he thought it most probable that this might be due to the varying length of the tube under different temperatures, as he did not think it would make any difference in this respect whether the moon was in perigee or apogee.

Mr. Hardwich had recently had an opportunity of visiting the observatory of Professor Challis, and photographing some of the spots on the sun. He knew he would have to contend with over-action of light, and took a bromo-iodized collodion as most likely to meet the case, and prepared his bath with forty grains to the ounce, as Mr. Fry did. He took also a very weak developer, consisting of about one grain of pyrogallic acid to the ounce of water. He had succeeded better than he hoped, and now handed round one of the prints for inspection. He noticed there was a strong halo surrounding the bright parts, similar to that seen round a meadow in taking an interior; this was the case with even the slightest exposure. This halation had been attributed to defects in the lens; but he thought that was not a satisfactory explanation, as it was more common with some kinds of collodion than others, and was rarely seen when a film of well-coagulated albumen was present. He would conclude by remarking, in reference to fused nitrate of silver, that he had been compelled to abandon its use, because he found it would not bear fusing, from the organic contamination in many of the commercial samples.

Mr. Sebastian Davis, referring to the different developers recommended by Mr. Fry and Mr. De la Rue, said that from some recent experiments he found a combination developer might be made possessing the advantage of the two. It consisted in mixing about ten grains of photosulphate of iron and one grain of pyrogallic acid in an ounce of water to which about one minim of sulphuric acid had been added. This prevented either discolouring or precipitation, and the detail of iron with the density of pyrogallic acid was obtained.

Mr. Malone, referring to the phenomena of halation, of which Mr. Hardwich had spoken, said it used to be frequently observed in daguerreotype practice. He suggested that it might be due to the action of the outstanding, uncorrected rays which were not brought to a focus. The subject was worthy of investigation.

Mr. De la Rue said he had found some difficulty in procuring nitrate of silver free from contamination with organic matter. The mode in which it is weighed and packed in paper he thought would readily account for the contamination. He found it the best plan to go to the refiners to procure it uncrystallized, taking care to prevent its contact with paper, &c., and then fuse it a little at a time.

The Chairman then announced that the photographic exhibition would be opened on Saturday to members and their friends, and on the following week to the public.

After the usual votes of thanks the proceedings terminated.

FRAUDULENT CHLORIDE OF GOLD.

BY R. REYNOLDS, F.C.S.

The consumption of chloride of gold in photographic printing is very considerable. As many chemists deal in the article, it is proper that they should be put upon their guard against frauds which have deceived several parties. I therefore give the results of the analyses of chloride of gold from three distinct manufacturers, which I have recently made, and although reserving the names of the guilty parties, shall probably take some future opportunity of examining their products.

All the samples referred to below were bought as chloride of gold, no mention of "non-deliquescent" being made by either buyer or seller.

The following are the results of the examination:—

"A. B."

Three "fifteen-grain" bottles taken at random, without removing wrappers. Contents were as follows:—

No. 1	11·7 grains
2	11·9 "
3	12·0 "
Average ...	11·87 "

One "sixty-grain" bottle taken as above, contents ... . 54· "

No. 1 was submitted to analysis:—

Gold, 4·4 grains = Terchloride of gold	6·75 grains
Chloride of sodium	3·80 "
Moisture and free acid	1·15 "
	11·70 "

As some makers of fraudulent chloride of gold reserve as a loop-hole the fact that the double chloride of gold and sodium is sold under the term of "non-deliquescent," and have the audacity to assert that no other is in the market, I give the composition which this should have had, even had it been the true double salt, although the preliminary notice shows that it was not sold as that. Terchloride of gold, 6·75 grains, would have combined with chloride of sodium 1·30 grains. Consequently there is an excess of chloride of sodium of 2·50 grains, simply diluting the mixture.

"C. D."

One "fifteen-grain" bottle taken as above, contents ... ... 15· grains

Analysis.

Gold, 7·25 grains = Terchloride of gold	11·12 "
Chloride of sodium	not a trace
Moisture and free acid	3·88
	15·

"E. F."

This was a solution labelled thus: "Neutral Solution of Chloride of Gold," guaranteed to contain 7 grains of pure gold, equal to 15 grains of crystallized "'non-deliquescent' chloride of gold."

Analysis.

Gold, 6·6 grains = Terchloride of gold	10·12 grains
Or = Chloride of gold and sodium...	13·26 "

The solution did not contain any chloride of sodium.

Practical Results.—Assuming "C. D." to be sold at a fair market price, the excess of profit over this to the maker of "A. B." is as follows, and of course, the loss to the consumer is the same.

On short weight	21· per cent.
(being average of three bottles)	
On lower quality	10·7 "
	31·7 per cent.

As, however, "A. B." was sold at 8·3 per cent. lower price, the sum will stand thus: 31·7 less 8·3 = 23·4 per cent. excess profit, or £23. 8s. on every £100 worth sold.

The samples "C. D." and "E. F," although not theoretically pure chloride of gold, may be considered to be commercially honest articles. The deliquescent nature of the pure chloride renders it a difficult operation to fill the bottles with accuracy as to weight, and the varying amounts of moisture which the maker may leave in the salt will always be a source of discrepancies in value.

The former difficulty may be overcome by sending out the solution instead of the solid chloride. I know of no reason why such solution should not be valued by its theoretical equivalent of gold, excepting that the practice of the trade has been going in another direction, and the change would involve an apparent, though not a real, advance of price to the consumer.

At the least, purchasers should require a guarantee of seven grains of pure gold in each bottle corresponding to the gramme, whether the contents may be solid or in solution.—*Pharmaceutical Journal*, Jan.

Miscellaneous.

Keeping Sensitized Paper.—A correspondent sends us the following:—Dry the paper thoroughly by heating it at a distance from the fire; get an ordinary pressure-frame, and some sheets of yellow tissue paper of the same size as the pressure-frame, when the paper is quite dry, lay it in the pressure-frame and put between each sheet of sensitive paper a sheet of the yellow tissue paper, which is better dried also before the fire, when you have sufficient paper prepared screw them tightly down in the frame, and put it in a dark and dry place. I have kept paper prepared by this method three weeks, which is a great advantage, as the weather has been so bad of late.

Shutter for Instantaneous Exposures.—Mr. J. C. Leake Jun., introduced at a recent meeting of the South London Society, a very ingenious and easily applied shutter for instantaneous exposures. It consists, primarily, of a slip of mahogany running freely in two grooved pieces of the same material, and placed directly behind the lenses, inside the camera. This slide is pierced with two holes exactly corresponding with the apertures of the lenses, but so placed, that when the shutter is quite up, to left or right, light is totally excluded from the camera. A brass hook is screwed into this and allowed to run through a slot in the front of the camera; a second hook being placed in the left hand corner, an elastic band is stretched over them both. The shutter now being drawn to the right, the elastic band is brought into a state of tension, in which it is retained by a brass lever. This, being pressed by the finger releases the shutter, the apertures in which pass those of the lenses, thus achieving the exposure. Mr. Meagher is, we believe, about to adapt this arrangement to some of his stereoscopic cameras.

Photographic Notes and Queries.

Amateurs and Professionals.

Sir,—I really don't like to occupy your valuable space on trivial matters; but I think the letter signed "An Amateur and Professional" ought to be replied to. I believe there are as many amateurs devoid of taste as professionals. I think any artistic photographer (say at some watering-place, where his sitters are both the highest and the lowest) will agree with me, that there are quite as many of the upper class who cannot appreciate a good photograph as of the lower. With regard to professionals taking the views in the winter, if they do, and they are well done, they have as much merit as if done in the summer; but I believe a professional with a love for the art will often sacrifice his more precious time in the summer to indulge his taste for landscaping. I have said his more precious time; why is it more precious? why should it not be as profitable for a professional photographer to take views as well as portraits? Is it because so many amateurs make it impossible? I know several amateurs who with double (by their salary) the takings of many professional photographers, take all their views for sale. They must think it sordid; for they seldom like their names mentioned: but, on the other hand, amateurs, with so much time at their disposal, take many beautiful views. If their object in publishing is to let the public have the benefit of them, I would suggest that all amateurs so inclined should publish their productions for the benefit of some institution, a hospital for instance; or let them be sold to form a fund for the purchasing of some good carbon or other process, or to award prizes for the best photographs; the ranks would soon be thinned of all tinkers, and tailors, or others, who had no talent for the calling. My advice to an Amateur and Professional is this; if he is an amateur, let him keep his productions to himself, or only amongst his nearest friends, and he will soon find professionals taking the same views, and equalling, if not excelling, his own: if he is a professional, and has realized such great profits by portraiture as to enable him to take a trip to London, by all means let him go. Before concluding, I hope all amateurs will think before they put their productions in the market, that they are on the point of injuring men who devote all their time (and their time is their money, as they depend on the art for a living) to photography, and are but badly paid after all. Apologizing for writing more than I intended, I am, sir, yours respectfully,

Fairplay.

[We give insertion to "Fairplay's" letter as a reply to "An Amateur;" but here the subject must drop, as it is not one for discussion in our columns. We can see no possible reason why amateurs should not make their practice of the art self-supporting, if not remunerative.—Ed.]

Talk in the Studio.

Photography on Wood. The wood engraving from a photograph on the block, to which we referred last week as illustrating the *Lyra Germanica*, was photographed by M. Joubert, by his phototype process.

South London Photographic Society.—At the meeting of this society which takes place on the 17th, T. Burr. Esq., F.R.A.S. &c., will give an interesting resumé of the aid which photography has afforded to astronomical and meteorological science.

The Phototype Permanent Printing Process.—M. Joubert announces his intention of making public the details of this process as soon as he has brought it to a sufficient state of perfection to be worked successfully by an ordinary workman. At present it requires considerable delicacy and manipulating skill to produce the best results.

Photographic Exhibition.—The exhibition of the Photographic Society opens in Pall Mall on Saturday to members of the Society, and on Monday to the public.

Architectural Photographic Exhibition,—The exhibition of the Architectural Photographic Association opens at the rooms in Conduit Street, on Tuesday, the 15th instant.

PHOTOGRAPHIC MEETINGS IN JANUARY.

South London	Thursday, 17th.
North London	Wednesday, 30th.
Blackheath	Monday, 21st.
Birmingham	Tuesday, 29th.

To Correspondents.

S. L. G—For lenses, No. 4 on your list. For cameras, No. 3. The plan you are adopting is an excellent one, and will well reward the trouble. If you send us your address we will communicate more fully in a letter.

J. R. A.—The law forbids *defacing* the coin of the realm; but that refers to what is intended for further circulation; we are not aware that there is any prohibition against using it for any purpose you like. As to the charge of "sweating" the silver, there is no ground for it; you need have no fear on that subject. The albumen process used by our correspondent Mr. Richards is the same as that described by our correspondent Mr. Archer, page 56, vol. 4 of the Photographic News, with a slight modification given at page 372, vol. 4. The same volume contains much information on the subject, as you may see by consulting the index.

B.—We are glad you have got over your difficulty. You will find it wise always to keep up the strength of the bath sufficiently. Your picture is a good and interesting one. Its only defect is the white sky. If that had not been stopped out the picture would have been all that could be desired.

A Young Beginner in Photography.—The only dictionaries of photography in existence are that published in our columns, and Mr. Sutton's dictionary, price 7s. 6d, published by Sampson Low.

Samson.—A negative collodion and neutral bath are best for the purpose. A low temperature is inimical to density. An argand oil lamp in your dark room will probably be sufficient to prevent your solutions from freezing; but it depends on the size of the room, &c. what effect it will have on the temperature generally. See an article on visiting card portraits in our present number.

James Tulley.—Any known method of printing by artificial light is somewhat expensive. The first article on the oxyhydrogen light is in the present number. See Mr. Malone's article on printing by the electric light in a recent number. A simple and cheap method is still to be discovered. The apparatus for the electric light, or any of the proposed artificial lights, is expensive to begin with.

Modest.—The charges of different artists vary materially. The cost of such negatives as you name would usually range from one to three guineas.

H.—We have never succeeded in getting a satisfactory coating of albumen by brushing, nor do we know of any method of effecting it. We have not tried the method to which you refer. The only plan we can suggest is to float and endeavour to save your albumen, so as to make it less wasteful. A little camphor added and light corking in a bottle would make it keep a little time this cold weather. Your only other rsource, is to buy your paper ready prepared, and take your chance of its quality. Try the use of arrow-root papers. We have seen some very fine results with it.

Florence W.—Most photographic processes are a little "messy" for a lady's manipulation, but they become much less so after a little practice. There are various modificications of the albumen negative process, and that of Mr. Archer is a very good one. Perhaps the following formula is a little more simple: to each ounce of albumen add a drachm of distilled water containing 6 grains of iodide of potassium, and to every 4 or 5 ounces add one drop of ammonia; beat the whole well and let it stand a day or two. When the plate is coated dry before a bright fire, excite in a bath of nitrate of silver 50 grains, glacial acetic acid one drachm, distilled water one ounce. Wash and dry. Develope with a saturated solution of gallic acid to which a few drops of aceto-nitrate of silver have been added.

T. K.—One of the difficulties in using the oxyhydrogen light is found in the management of the lime cylinders. They will always have a tendency to crack. To avoid this as much as possible always keep them, when not in use in a stoppered bottle to prevent absorbing moisture from the atmosphere. When first using them warm through gently, to expel all moisture, before applying much heat. And, when in use, keep them constantly turned round, as if the flame plays long on one part, it will certainly decrepitate. See articles on the subject.

H. T. B.—The general plan of your house is very good, and we have only one or two suggestions to make. In the first place you will find that the height of the house is too limited generally; if possible, have a few feet greater height throughout. In any case, the proposed "pitch," or slope will be insufficient to keep out wet. It is very important to have sufficient pitch to throw off water at once; without this you will always have leakage, and an accumulation of dust and dirt. On the side where you have no light use a reflecting screen covered with white calico, or what is better, tin foil. This gives a pleasant reflected light, but requires care to avoid too strong a reflection in the eye of the sitter. You will do well to read the description of a glass house in No. 59. The number is in print and can be had without purchasing the volume.

T. P.—You may mix your silver baths without disadvantage; all the free nitric acid may be converted to nitrate of silver by the addition of oxide of silver to the bath. Sheets of bright tin soldered together would make a good reflecting screen, but would require skilful management to avoid getting the reflections too strong, especially in the eye of the sitter. Tin foil glued on to wood would be better.

Stereoscopic Exchange Club.—The member exchanging with N C. Camm, late of Nailston Rectory, will please note that his address is now Well Holme, Brighouse, Yorkshire

J. W. S.—The terms orthographic, orthoscopic, and caloscopic, are given by different makers to similar lenses.

Lex.—The rapidity of a lens, other things being equal, is generally greater in proportion to the shortness of the focus.

F. B. L.—Iron developement usually gives more softness and detail; pyrogallic acid more intensity. The former is generally difficult to use for dry plates.

James Spencer.—There is no necessity to add alcohol to new nitrate bath; and whilst the bath is new, you will not need much alcohol in the developer. You must gradually increase the proportion in the developer as the bath becomes old charged with ether and alcohol.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 124.—*January* 18, 1861.

THE PHOTOGRAPHIC EXHIBITION.

The annual Exhibition in connection with the Photographic Society is naturally regarded as the epitomized and embodied record of the year's photographic progress; of its scientific discoveries, its practical improvements, and its advance in art-culture. What men of science or practice have proposed, what societies have discussed, and what journals have suggested, recorded, examined, and criticised, we here hope to find in practical results, and, in a very literal sense, "teaching by example."

The eighth annual Exhibition, which was opened for a private view on Saturday the 12th, and to the public on Monday, at the Gallery of Water Colours in Pall Mall, whilst it meets this view very fully in some respects, is scarcely a satisfactory exponent of the year's progress as a whole. Our first impression, after a general inspection on Saturday, was one of almost unalloyed pleasure. We were so agreeably surprised at the general excellence of the exhibited pictures, after a season in every way so unfavourable for the production of good results; we were so well pleased with the *material* qualities—excellent processes, excellent manipulation, excellent lenses—the existence of which so many of the pictures proved; and above all we were so delighted with decided art-progress so abundantly manifested, that we willingly echoed the general remark, "What an excellent exhibition!" It is only on a second and more reflective examination, that the absence is felt of much that is necessary to a complete embodiment of the year's results. There is absolutely scarcely one important novelty exhibited; nor are there specimens of progress of many important branches of the art. There is no specimen of photo-lithography or photo-zincography, although two or three distinct processes have been brought to a very high state of perfection during the year. There is no specimen of carbon printing. There is no specimen of M. Joubert's process of photographic enamelling. There is no specimen of Mr. Sutton's panoramic photography. There is scarcely a specimen to mention of celestial photography notwithstanding the amount of interest attaching to it, in connection with the eclipse of last July. There is scarcely any example—none specified—of the productions of the solar camera. The only novelty of importance is the process of block-printing by Herr Pretsch, of which some promising prints, and the blocks from which they are produced, are exhibited. There are also some specimens exhibited by M. Claudet of photographic portraits in "enamel colours, burnt in by the process of M. Lafon de Carmassac." What part photography plays in the production of these we are not informed; they are exquisite enamel paintings, but by no means examples of photographic veracity, if the portrait of Her Majesty the Queen be regarded as a fair specimen. With the two exceptions we have quoted, there is no novelty whatever; no evidence of the extension of the powers or applications of photography to fresh branches of science, art, or commerce; the whole of the six hundred and twenty-two frames exhibited containing specimens—for the most part very good specimens—of the ordinary and well known processes of photography.

The result of an analysis of these six hundred and twenty-two specimens is somewhat singular. Of the total number not less than five hundred and fifty-two are by the wet collodion process; twenty-eight by the collodio-albumen process, of these twenty-eight, seventeen are by Mr. Mudd; twenty by the metagelatine process, eighteen of these being by Mr. Maxwell Lyte; eight by the Fothergill process; nine by the waxed paper process, of which eight are by the Rev. T. M. Raven; two are by the malt process; two by the honey process; and one by the oxymel process. Whilst the wet process claims such a pre-eminence in the number of its representatives, we can by no means accord to it the same position as to excellence; the number of specimens being borne in mind, dry collodion takes much the foremost rank. It is a somewhat invidious task to award the palm of highest merit where there are a dozen of unexceptionable artists; but deciding by the specimens now exhibited, we should give decided priority to the works of Maxwell Lyte, James Mudd, and Francis Bedford; or to Mudd, Bedford, and Lyte; or to Bedford, Lyte, and Mudd, for the three are equal. The specimens of these gentlemen represent three distinct processes, the wet collodion worked by Mr. Bedford, the collodio-albumen process worked by Mr. Mudd, and the metagelatine process worked by Mr. Lyte. Nothing could be a more satisfactory verification of the idea so frequently enunciated in these pages, that it is not so much in processes, as in the cultivation of artistic taste and manipulatory skill that excellence depends. The pictures of each of these processes, abound in everything, constituting good pictures; the most perfect photography guided by thoroughly artistic feeling. We might mention a host of others whose productions are scarcely inferior: Fenton, Robinson, Bisson Freres, Wilson, Wardley, Bourne, Cundall and Downes, Heath, Campbell, Dovizielli, Fry, Gillis, Piper, and others.

The general impression the Exhibition conveys is, that it is a very full one; and although containing so many pictures of equal merit, that it is on the whole as very well hung as the limited size of the room will permit. Those pictures possessing manifest pre-eminence in merit have generally the best positions, and we have not noticed, hitherto, any picture especially deserving examination that is hung beyond the reach of such scrutiny.

Amongst the most noticeable pictures, especially as to size, are some immense pictures by P. Dovizielli; one of the Coliseum at Rome, (30,) is especially fine, and a very perfect vigorous photograph: it possesses, alas!—for we must always express our feeling on this subject—a white-paper sky. St. Peter's, Rome, (52,) is a similar picture with scarcely as much merit.

One of the next features that strikes us is the increase in the number of reproductions, especially from paintings. We must confess to a considerable pleasure in this fact, as we regard this as capable of becoming a still more important branch of photography, and think it worthy of every effort to overcome the varying photogenic action of colour, so as to secure perfect results in this direction. Where this can be done, reproductions, giving the exact touch and drawing of the master, must, as we have before observed, possess a value and an interest impossible to attain by any other means. Amongst those excelling in this department, Messrs. Cundall and Downes occupy a foremost place in this Exhibition, followed by Ponting, J. Hogarth, jun., Dovizielli, Caldesi, Hering, and others.

In the centre of the wall at the top of the room—by common consent regarded as the place of honour—is hung Mr. Robinson's "Holiday in the Woods." We congratulate

Mr. Robinson on several points in connection with this picture: in the first place that he has printed it so well. We remarked in our recent criticism on the composition that we were sure Mr. Robinson could produce a better picture from the same negatives: in the print now exhibited, he has certainly done so, and the result is almost faultless; rich and harmonious in tone; at once atmospheric and vigorous; artistic and natural in grouping, fine in chiaroscura, it stands prominent amongst surrounding pictures, as full of life and sunshine. Its effect is much enhanced by the excellent taste of the mount and frame. We congratulate Mr. Robinson on the real excellence and on the general effect, and especially on the high appreciation it has received both from the general public and connoisseurs. We have but one fault to find: the price —twenty-two shillings—is altogether inadequate; it is worth two or three times the money, and we should scarcely conceive that it can be remuneratively produced for less. The Top of the Hill, (465,) by Mr. Robinsou, is also a very fine picture.

Mr. Mudd exhibits a number of such charming pictures, so well selected from such lovely spots, so carefully manipulated, and withal pervaded by so much real artistic feeling, that it is difficult to individualize and say this or that is best. There are two, however, that especially rivet our attention each time we approach: the first, "On the Greta, Robely Park," (103) is full of poetry; we never tire of looking at it, and although not a large picture, we are much disposed to regard it as the gem of the Exhibition. The second, scarcely inferior, is entitled, "In Teesdale," (183.) Mr. Mudd's landscapes throughout, apart from the excellent photography, are charactenised by a delicacy of treatment and fine artistic feeling, rarely equalled.

Mr. Fenton is a large contributor, and amongst his contributions are some wonderful studies of still life, which for admirable grouping, delicacy, softness, and truth, have never been equalled. A contemporary has remarked, "How delighted Lance would be with these!" We have heard it whispered—and we repeat the whisper in no derrogation to the photographer—that Lance had really grouped some of the studies. Be that as it may, they are worthy of him, and well worthy of the fame Mr. Fenton already possesses as an artist-photographer. The delicate bloom on the magnificent fruit, the graceful blending of the exquisite flowers, the crisp carving of the ivory casket, are altogether inimitable. In the resolute determination to avoid the common sin of such subjects—hardness, there is, perhaps, in some of these a slight tendency to a uniform looseness of tone and want of vigour, especially where the sparkling high lights of cut glass are rendered by flat tints of grey; but we may mention one, "A study of fruit, &c." (150), that is quite free from this fault or any other: it is full of delicacy and softness, combined with brilliancy; and the grouping is, we think, absolutely perfect. In landscape, Mr. Fenton is scarcely to felicitous as usual; and this fault of monotony, heaviness, and want of vigour, is, in some specimens, painfully apparent. They are valuable, however, as illustrations of the power the photographer may really possess in this direction, which is not a common one to err in.

Mr. Wilson has contributed some of his charming instantaneous effects, small in size, as gems often are, but exceedingly beautiful.

Mr. Bedford's pictures, of which there is a goodly number, are all fully equal to his own standard, and that is saying much; some indeed surpass what we have before seen.

Mr. Maxwell Lyte's pictures are the finest we have seen him exhibit; in one especial characteristic we think they take the lead of the exhibition: we refer to breadth and richness of chiaroscuro.

Mr. Fry has some good pictures of which, perhaps, the best is St. Nicholas Church, Brighton (92). This is a large picture, 16 by 12, we think, very brilliant, vigorous, and perfect as a photograph. The introduction of natural clouds from a separate negative—the legitimacy of which, is at the present moment a moot question—is here managed with excellent effect and contributes to the harmony of the picture.

A very charming picture, the auld Brig o'Doon (433), which Burns has rendered immortal in his Tam O'Shanter, is exhibited by Mr. David Campbell.

In portraiture the Exhibition is not one whit in advance of previous years; we should scarcely err iu saying it was not up to the former mark. Some of the best portraitists have, for some reason or other, abstained from exhibiting this year; and some who do exhibit have made no advance whatever, whilst the art *has* progressed. Maull and Polyblank exhibit several portraits which are as good as those of some years ago, and no better. Mr. Wright, who writes himself "artist and photographer," exhibits some portraits which prove he has much to learn in both branches of his profession. Messrs. Caldesi and Co. exhibit a very charming portrait of a lady (447) which, despite some faults in the background accessories, possesses many qualities worthy of attention. Mr. Hering has a frame of portraits of children, exquisite in pose, expression, and general delicacy of treatment.

Mr. Claudet has some very fine coloured pictures; amongst them an enlarged portrait of Lord Macaulay, coloured in oil which excites much attention. This picture possesses sufficient that is excellent to make us regret exceedingly that it is as a whole a failure. It is in the first place enlarged to a size just below that of life; which is, therefore, suggestive of boyhood; and the colouring, although fleshy and natural in hue, has so far destroyed all the strong lines and characteristic markings of the face, as to add very materially to the boyish effect of the size; whilst the grey hair has a singularly incongruous effect in conjunction with the general aspect of juvenility.

There is a large display of *cartes des visite*, as it has become the fashion to call these Lilliputian portraits. (Are they really ever used as such?) Many of them are very good: perhaps those exhibited by the London Stereoscopic Company are the finest; the mounting of these latter are deserving of especial praise.

We have already more than exhausted our space in giving some brief hints of our first impressions. In future articles we shall return to the subject in more detail and regular order.

We miss from the catalogue many of the old names which used to grace it, amongst whom we may mention Rejlander, Rosling, Lake Price, Grundy, Llewellyn, White, Williams, Delamotte, Frith, and others; aud we miss, also, some of the processes which at one time were represented: but in no other Exhibition do we remember such a prevalence of real pictorial excellence, so few white skies, and so little "soot and whitewash."

EXHIBITION OF THE ARCHITECTURAL PHOTOGRAPHIC ASSOCIATION.

THE Exhibition of photograpns of architectural subjects in connection with this association was opened in Conduit-street, on the evening of Tuesday, the 15th instant. As a whole the Exhibition is superior to that of any former year, and displays a greater number of fine interiors than were perhaps ever exhibited. We find the familiar names of Bisson, Fenton, Bedford, Mudd, Dollamore and Bullock, and others, and we are glad to add especially, Mr. Frith, who puts in no appearance at the Society's Exhibition. There are some exquisite interiors of Canterbury Cathedral by Mr. Austin, a gentleman whose name we do not remember before to have met with, but who possesses especial excellence in this branch of the art. We shall notice the Exhibition in detail in a future number.

PHOTOGRAPHIC BLOCK PRINTING.

In a recent article, entitled "A Glance at Photography in 1860," referring to Herr Pretsch's process of surface printing by blocks, produced by the combined aid of photography, and the electrotype process, we remarked that "the first specimen we saw, which was printed with great care, and issued in the *Journal of the Photographic Society*, possessed many excellences, and was full of promise; the last specimen issued, in our Liverpool contemporary, was so much inferior, that it tended to destroy that promise."

Our contemporary thinks there is some unfairness in this notice, and states, that "if the editor possessed the necessary technical knowledge, in common fairness he ought, for Herr Pretsch's sake, to have stated the whole facts." Those facts are, that the first named specimen was printed at the ordinary printing-press, not in conjunction with other type, and the latter was printed by machine, "made up in forme." with the ordinary type of the *Journal*.

Now we must state at the outset, that our contemporary has, not willingly we hope, misconceived us, and proceeds to speak of the *two* specimens which appeared in that *Journal*. We only referred to one, the latter. The first specimen which appeared in the *British Journal*, we unhesitatingly and with pleasure admit, was full of promise. We did not refer to it, for this reason: we were not entering into any general criticism of the subject, but "glancing" at it, and therefore referred to the best and worst specimens. We were not referring to the qualities of the printing at all, but simply to the subjects, and to us it was so much a matter of course to note and allow for the technical differences in production, that we should never have dreamed of it being necessary to say we had done so. A quarter of a century's constant familiarity with the penetralia of a printing-office, is apt to breed a slight obliviousness of the necessity for technical explanations, which to persons whose knowledge of the subject is more limited and exoteric, appear, and really are, important. We will, therefore, state a few details, for the information of our readers.

In the ordinary process of letter-press printing, wood engravings are generally the subject of especial care: and where artistic excellence exists in the engraving, and is required in the prints, many hours are frequently spent in the process of what is termed "making ready," in order to "bring up" the block so as to secure the full rendering of all its beauties. This is work which belongs to the "pressman," after the engraver has completed his part of the labour; it consists chiefly in what is termed "overlaying," &c., and is somewhat similar to the stopping out, masking, &c., of the artistic photographic printer, the object being to secure increased pressure on parts requiring especial force and vigour, and less pressure on the more delicate and tender parts. This done, the printing is usually effected by the ordinary hand-press, in conjunction with letter-press or not, as may be required, and, where the best results are desired, with extra good ink and on good paper. Where the quality of the work is of less importance, it may be printed by machine, but the same excellence is not attainable in that case even with the utmost care. Until recently it was not considered possible to print wood engravings by machine with any degree of success; but the improvements of late years in machines, made especially for that purpose, to meet the wants of illustrated papers, have effected a considerable revolution in this respect. In blocks especially cut for machine printing, a certain style is adopted in the engravings, suited to the peculiar exigencies of the case; and where the best effect possible with the machine is aimed at, an especial arrangement exists for the prevention of what is termed by the printer "setting off," a defect which issues in the blurring of a part already printed by the pressure of printing on the opposite side. Still, where the best results of which an engraving is capable are desired, the hand-press is invariably used.

Now the specimen of Herr Pretsch's process, issued in the *Journal of the Photographic Society*, was printed by hand-press, and, as we may reasonably suppose, with all the care usually given to first-class wood engravings: the specimens issued by our Liverpool contemporary were both printed by machine, the first by a "platen" machine, the second by the ordinary "cylinder" machine. The "platen" machine, we must explain to our readers, most nearly approximates to the character of the hand-press, inasmuch as the pressure on the "forme" is effected by the steady descent of a flat surface, or "platen," as in the ordinary printing-press; whilst in the "cylinder" machine the pressure is effected by a revolving cylinder; and there is more tendency to blurring, and less delicacy in the impressions, a thinner and worse quality of ink being generally, also, necessary in working it. Wood engravings of any artistic value would scarcely ever be printed by such a process. We make these explanations thus fully, because we have no wish whatever to conceal the fact, that Herr Pretsch's blocks were, in the *British Journal*, submitted to a most crucial test; and that the first of them, moreover, making allowance for all this, although not equal to that in the *Society's Journal*, was still full of promise.

Having said this much, however, we must repeat that, all allowances for method of printing being made, the last specimen in the *British Journal* was so inferior, that it tended to destroy the promise of the first specimens, and that simply because it was an unhappily chosen subject for the powers of the process in its present stage. That has been the opinion we have heard universally expressed, both by photographers, artists, and connoisseurs. We regret this the more, because, believing that the process is destined to take an important position, this specimen has produced a most unfavourable impression in the minds of those who are interested in the results, but insufficiently familiar with our art to understand the cause of the failure. From such an observer, holding some position in the art world, we heard the exclamation very recently, that nothing he had seen had so much illustrated the poverty and weakness of photography in this direction, as the illustration in question. We believe that the process is capable of improvement, and that for certain subjects it may even now be made valuable; but we cannot but regret the damaging effect of asserting that the last issued specimen, all drawbacks of printing being admitted, is a fair specimen of the powers of the process. That Herr Pretsch is not of that opinion, may be fairly assumed, from the fact that no specimen of that block appears at the present Exhibition, whilst prints of both the former specimens are exhibited.

We will here add our conviction, with due deference to the opinion of Herr Pretsch, at whose wish our contemporary states the block was so printed, that the test was an unfair and an unwise one, to submit a specimen of a *new* process of engraving to a method of production, which would never be adopted with an engraving of any merit, even where all the appliances of the engraver could be brought to bear in preparing it for the operation.

Since writing the above we have received a very courteous communication from Herr Pretsch, in which it is evident he has come to the conclusion we have above stated, for in intimating the pleasure he will have in placing one of his blocks at our service, the only stipulation he makes is, that we "will bestow on it the attention necessary for printing a fine wood engraving." We hope shortly to present our readers with a specimen, in the production of which the necessary care shall be bestowed.

We have a final word in regard to ourselves. Our good friend the conductor of the *British Journal* thinks we are "rather prone to 'hint a fault.'" We must confess we are rather at a loss to grasp his meaning here. The only fault referred to — the damaging character of the specimen mentioned—was broadly stated, not "hinted," That, in our interest in the fair appreciation of the process, we should point out such a fault, we think Herr Pretsch himself will readily pardon us, if pardon we need. That any fault in the matter, as regards our contemporary, was not either stated or hinted, is to ourselves quite clear; in any case he may accept our assurance that none was intended. When we have to deal with any fault it concerns us to point out, we will not indulge in

"—the kind mendacity of hints,"

but state them honestly and fairly, in the conviction that we are speaking to honest and fair-dealing men, with a common cause at heart, and who will appreciate all legitimate and straightforward efforts to serve it.

Notes and Jottings.

No. IV.

Photo-lithographic Process founded on M. Joubert's Patent for Enamelling on Glass.—Ordinary Photographic Printing in Permanent Colours from the same Source.

The publication of the particulars of M. Joubert's patent for burning the photographic image into glass, suggested to us the idea of adopting similar means for producing a drawing on stone, to be printed from in the lithographic press.

It will be remembered that M. Joubert employs a salt of chromium, in solution with albumen and honey*, which is rendered hard and insoluble when acted on by light, whilst the protected portions retain an adhesive, sticky, surface, to which some vitreous colour is made to adhere, on being applied with a large camel-hair brush.

The method was adopted in our incomplete experiment, was as follows: a piece of paper was coated with a mixture of bichromate of potash, ammonia citrate of iron, albumen, honey and water, and exposed when dry, under a transparent positive. On removal from the printing frame, the portion acted on by light was seen to have been rendered hard and insoluble,—the other portion retaining its stickyness, as in the case of M. Joubert's glass plates. But instead of a vitreous colour, we used a resinous gum, in which to bring out the image, the adhesive nature of the honey in the unexposed parts holding it fast.

A finely grained lithographic stone was then taken, and the paper, image downwards, placed thereon; then a moderately warm iron being passed over it, caused the resin to adhere to the stone. Removing the paper, a solution of gum arabic with a very small quantity of nitric acid was allowed to remain on the stone for some little time, and then washed off under the tap. A charged roller being now passed over, the ink adhered to the resin only.

The above remarks are crude and inconclusive, but as at the present time many are experimenting in photo-lithography, we give the result of our research so far as we have gone. Unfortunately, for some short time to come we shall not have access to a lithographic press to continue our investigations.

Taking the same process of M. Joubert's for a starting point, we found it possible to produce a positive print on paper in permanent colour.

A paper was prepared and exposed as in the above case; then, on a stone in the lithographic machine, a portion of the desired pigment, dry and finely ground, was placed, and on it, face downwards, the exposed paper. On passing once or twice through the press, with a moderate, equal motion, the sticky parts were found to have taken up the colour. After coagulating the albumen, the chromic salt was got rid of by soaking in water containing a small portion of carbonate of soda, which, however, caused a slight loss of half tone.

Michael Hannaford.

The Technology of Art as applied to Photography.

by Alfred H. Wall.

Adherence.—A term used to express a want of due relief in a picture's various objects or planes of distance. The word's literal almost explains its technical meaning, although for the purposes of descriptive criticism it is frequently found very serviceable. The defect it represents is by no means an uncommon one in photographic productions. This may arise from the mismanagement of a lens; but it is perhaps more frequently due to a want of artistic taste and knowledge in the operator; who, by obtaining an undue amount of density in the negative, destroys the delicacy of the ærial tones, and thus loses the effect of space. Over printing may also produce such effects, even from a negative of the finest pictorial quality, by simply destroying the detail and vigour of the foreground with a view to giving increased depth and intensity to the more distant parts; which being thus strengthened and rendered harsh, seem unnaturally near to the spectator. Adherence, in landscapes particularly, implies the absence of space or air, which can only be represented pictorially by the delicate influence expressed in the softened and less defined character, or proportionate absence of detail, and the tender gradations of the lights and shades. The too common desire for sharpness in every part of their productions, so commonly expressed by inartistic photographers, is not only opposed to scientific truth, but is utterly destructive of pictorial beauty. In destroying these atmospherical effects, we lose the tender gradations of tone by which the sky and landscape are so sweetly united—the simple grandeur of that all-important quality, breadth—the power of relief, and the poetic influence of harmony or keeping, of which ærial perspective is a most important element. And what is given in exchange for this terrible loss? Simply that which has been so much lauded under the terms *sharpness* and density, of which adherence is the offspring, and are only other words for hardness,—a quality only fit for maps, micro-photographs, and geometrical designs. *Truth, loveliness, and sentiment*, plead with photographers against that hard, cruelly cutting quality *sharpness**. Pray let them not plead in vain. The quality of adherence may sometimes arise from the use of an old collodion, the peculiar condition of the bath or the character of the developer, as these also are liable to give too great an amount of density. A continual source of this defect (adherence) in portraiture, is to be found in the use of what is termed the "French" or "cut-out and printed-in" backgrounds, which, giving a smooth, even, and perfectly flat effect, suggestive of an inlaid condition, rather than that of relief or space, must always be offensive to good taste; even if the staring horror of the cut-out edges substituted for the imperceptible boundaries of vision, be with the aid of an artist's brush somewhat softened. (See also *atmosphere, distance, and relief.*)

Adjustment.—A word which is frequently applied to the choice, arrangement, and disposition of drapery. Although various materials have their individual peculiarities of shape in the folds and breaks they assume, yet, when skilfully arranged with reference to the composition of lines, and the breadth of chiaroscuro, the pictorial result may be very considerably improved; indeed much more so than a mere mechanical operator, who never aimed above indiscriminate copying, would, without seeing, very readily believe. The larger folds of drapery, when confined to the more prominent portions of the figure, do much to aid relief. The smaller folds, by breaking up the masses of light and shade into streaks and spots, destroy breadth. Here the printer may do much by regulating the depth and intensity of shadows, thrown by folds falling within that space of the drapery which is most strongly illuminated, and those folds retiring from the eye, or falling into the general mass of shadow, as his taste, skill and knowledge may suggest.

Adventitious Effects.—Such effects as are foreign to the nature of the chosen subject, although they may be attractive and pleasing in themselves, and even extremely valuable to the picture's general effect, are so called. Such should

* Our esteemed contributor is perhaps open to a little misconception in regard to the term "sharpness." He has no quarrel with the perfection of the quality in its proper place; but with the aim to produce it in a photograph, when to natural vision it would be impossible, and with the disposition to make it take the place of all other and higher pictorial qualities.—Ed.

not be chosen or introduced, however, without the exercise of more than usual care.

Ærial Effects.—A term which, in its more general sense, bears reference to ærial perspective; but which is also frequently used as bearing more especial reference to the various accidental effects arising from certain peculiarities of atmospherical condition. This term is also used as descriptive of effects in which the artist, to secure a supernatural or dreamy, indefinite result, substitutes an ærial character for the qualities of solidity, opacity, and weight. In photography such effects are obtainable by the very simple and well-known method used for the introduction of ghosts, angels, &c.* When the atmosphere, being more than usually charged with moisture, possesses a greater amount of density, it will give to certain scenes various peculiar charms which they possess at no other time, and these will be more commonly recognised by the painter under the term of our text. A similar effect is also produced when the opacity of the atmosphere is increased by being more directly under the influence of direct sunlight. Ærial effects are frequently very novel and picturesque, and although they more properly belong to the accidental category, are quite as frequently described as ærial,† and certainly are connected with both.

Æsthetics.—This term indicates the philosophy of the beautiful. Being adopted into art nomenclature, it is received as indicating poetical or refined feeling and sentiment. The theory of the beautiful, however, is so frequently lost in a species of metaphysical mist, that photographers, being essentially practical in their general ideas, may be disinclined to give to it that attention which nevertheless it fairly deserves; for the philosophy and poetry of all fine arts must be of importance to those who desire that their works shall express the higher qualities of such productions, whether such works be executed with ink-pen, paint-brush, or sun-pencils. The appointed limits of these papers do not now permit us to dwell upon the importance of such an interesting and useful, although somewhat complicated branch of study to the photographer; but such knowledge once obtained would be found to be as important to photographic as to brush art. The term, compounded, we believe, from the Greek and French, was first used by Professor Baumgarten, of Frankfort-on-the-Oder.

Ærial Perspective.—This treats of the natural appearances presented by objects as they retire from or advance towards the spectator, such appearances being regulated by the quality or amount of the interposed atmosphere. As forms recede from the eye, their lights and shadows are weakened, their local colours degraded, or changed, and their details lost. The opacity of the atmosphere is increased by the amount of humidity, and by the quantity of light which it contains; although, in the latter case, objects do not appear more distant than in a less strongly illuminated medium, because the distant forms are rendered more distinct by being more powerfully lighted. We have certain settled laws of ærial perspective, but, as they continually vary with the changeful character of the atmosphere, they can only be properly learnt by an attentive study of nature. This all-pervading medium it is that limits our field of vision, interposing veil after veil between us and the retiring distances, until the various features of the landscape, being gradually softened and obscured, at last melt away into that vast ocean of atmosphere in which our world itself exists and has its being. The rapidity and influence of atmospherical changes, in connection with landscape painting, is well known to the artistic student of nature; but with photographers this appears to be less recognised, although to them of even more importance, inasmuch as by them ærial perspective is too commonly neglected, as a something which it is quite unnecessary they should know anything about. Landscape photographs, however, being, as I have shown, liable to the fault of adherence, which in their case implies the absence of air, it is evidently a necessary branch of photographic study. Besides, without such a knowledge, how can we test the truth of our productions, which are too much at the mercy of optical, chemical, and manipulatory errors, to be *necessarily* true.

* See page 11, vol. I.

† So much carelessness has been displayed in the application of these and other terms of art, both by painters and critics, that already we foresee that we shall frequently be puzzled to explain the real ideas more commonly implied by certain terms without apparent repetition

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATIONS, AND ANALYSIS.

IN the first chapter on this subject it was mentioned that there were two methods for the conversion of the precipitated crude nitrate of silver into pure metallic silver, one of which was described; the other plan, which will be found in many cases even preferable to the plan already given, is the following:—

2. After all the free nitric acid has been driven off from the crude solution of the silver coin in nitric acid, add as before specified to the mixed nitrates a little distilled water (quantity immaterial), and allow it to stand till all is dissolved. Next procure a sheet of copper of sufficient thickness to bear handling without easily bending, and large enough in area to stand upright in a pint jug (say three inches by four). If it be inconvenient to employ such a piece of copper, two or three copper coins suspended by copper wire will answer the purpose; but in all cases the surface should be rendered perfectly clean and bright. For this, immerse the copper sheet or coins for a few seconds in warm dilute nitric acid until the surface is entirely covered with a multitude of very minute bubbles, then remove it and well wash under a tap, and give a final rinse with distilled water. The crude nitrate of silver will by this time have dissolved; add distilled water to the solution in sufficient quantity to make up about half a pint of liquid, and filter into a perfectly clean pint jug; wash the filter well with distilled water, and then place the cleaned copper sheet or coins in the green solution. Immediately a beautiful precipitation of metallic silver in needle-shaped crystals will take place, which will grow in length and bulk until they drop off the copper and are replaced by others. In this manner all the silver will gradually be reduced from the solution, and its place taken by the copper. The complete reaction, however, requiring some time to effect, it will be advisable to cover the jug over with a plate or other cover to keep out the dust, and to place it in a rather cool oven or on the hob for a few hours, in order to make sure that all the precious metal is precipitated. When this is judged to be the case, lift up the copper from the liquid, and with a glass rod or silver spoon gently detach the crystals of silver which are still adherent to the surface of the copper, but not employing sufficient force to rub off any of the latter metal.

When all the silver has settled to the bottom of the jug, gently pour off the supernatant liquid, and test it to see if there be still silver in it by adding a few drops of solution of common salt to it. If there be no white cloudiness produced in the liquid after standing for a few minutes, it may be considered as free from silver, and may be thrown away. If, on the contrary, a precipitate is produced, it shows that all the silver has not been thrown down, and the copper must be again introduced. Supposing that the precipitation has been complete, the jug must be filled up with hot water (common water will do at first), and the silver well stirred about in the liquid with a silver spoon, and then allowed to settle. The water must then be poured off, and the washing operation repeated for several times. Afterwards it must be washed in a similar way with dilute hydrochloric acid, and then with dilute ammonia, always finishing by two or three washes in distilled water until the liquid, which is poured off, ceases to be alkaline from the presence of ammonia. These various washings, &c.,

may seem tedious; but they are necessary, in order to be sure that the last traces of copper have been removed from the solution. The time occupied about them is, moreover, not much longer than is required to read these instructions, as the metallic silver settles very quickly. When the last washing has been accomplished, the silver will be in a perfectly pure state, ready to be dissolved in nitric acid, and converted into nitrate in the manner directed in our first chapter on this subject.

Mention was previously made of a black or brown powder which sometimes remained when the crude silver was dissolved in nitric acid, in the first instance. This is metallic gold, and in cases where the silver has been of old manufacture—old coin, plate, &c., it frequently is in such quantity as, to become worth extracting. Being insoluble in nitric acid, it is left behind when this metal is dissolved, and may be separated by filtration and washing. As the amount from one operation will, however, be scarcely sufficient to make it worth while to convert into chloride at once, it will be best to preserve it in a bottle until fresh accumulations from the silver residues (which likewise usually contain most of the surplus gold which has not found its way down he sink), have rendered it sufficient to be worked up with profit into an available form.

The processes above given will yield nitrate of silver in the form of a dry white powder; it will, however, be preferable in some cases to have it in the crystalline form; this can be easily effected. Dissolve it by the aid of heat, in twice its weight of water, employing a clean saucer for this purpose, and the water-bath arrangement mentioned in our first chapter. When it has dissolved, filter it; if necessary evaporate it to half its bulk over the water bath, and place the saucer on one side in a cold place for a day, keeping it well covered over with a sheet of paper. At the end of that time the bottom of the saucer will be found to be covered with an abundant crop of fine tubular crystals of nitrate of silver. Gently pour the solution off into another smaller saucer, and tilt the one containing the crystals on one side so that the liquid may all drain away; support it in this position and cover it with clean paper to keep away the dust, and let it remain undisturbed until the liquid has all drained away, and the crystals are quite dry; break them from the bottom of the saucer with a glass rod, and transfer them to a clean stoppered bottle. The solution drained away from the first crop of crystals will yield a further supply, if it be a little more evaporated over the water-bath, and then set aside, as above directed. The remaining solution—the mother-liquor—drained from this second crop, had better be evaporated down to dryness, and employed for positive printing. It ought to be pure enough for the negative bath, if all our directions have been properly attended to, and good and clean materials used; but as any accidental error or impurity will tend to render this residual quantity rather less pure, it will be advisable not to employ it in cases where absolute purity is essential.

If it be desired to carry the refinement to the highest possible point (although to our mind purifying an already perfectly pure salt, is about as useful an employment as gilding refined gold, or painting the lily), the nitrate of silver may be *used*. For this purpose it will be useless to take the salt crystallized as last recommended, although some operators advise that; but the dry residium remaining after the solution of the purified silver in nitric acid has been evaporated down, may not unfrequently be fused with advantage. If the nitric acid be not pure, or there is a doubt whether organic matter has got in, fusing will be beneficial. For this purpose, scrape the dry salt out of the cup, by means of a silver spoon, and transfer it to a thin unglazed porcelain dish, used for chemical purposes. (A dish must be purchased especially for this, as common earthenware, or china, will be attacked by the fused salt.) When all the salt has been placed uniformly over the bottom of the dish, cover the latter with a large piece of mica to keep out dust, and still enable the operator to watch what is going forward; and then, having supported the dish on a convenient support (a metallic triangular plate-holder on three legs is as convenient a support as any), gently warm it with a spirit lamp. In a short time the mass will commence to liquify, and gradually the whole will become fluid. The heat should be continued until there is not a solid particle in the dish, but not long enough to cause any evolution of bubbles, as that shows that decomposition is beginning. As soon as it is all quite liquid, remove the source of heat, and allow it to cool. When quite cold, dissolve in twice its bulk of water, and crystallize in the manner recommended above. The first two crops of crystals—if the operations have been properly conducted—may be looked upon as the purest form of nitrate of silver which it is in the power of chemistry to produce.

PHOTOGRAPHY WITHOUT A CAMERA.

A photographer without incumbrances would be the happiest of mortals. Could he but start on an excursion with as portable an outfit as a sportsman or an angler, his vocation, now so serious, would become a mere pastime. By the rapid and remarkable progress photography has made within a few years, the fruit of the experience of numerous skilful artists, aided by ingenious constructors of apparatus, we have attained unhoped-for results. Yet this supreme success is not accessible to everyone engaged in the practice of the art, but still remains the privilege of those masters who have devoted long years of patient labour and intelligent skill to the perfecting of methods and processes.

Among the impediments to the universally successful practice of photography, the most important to the peripatetic artist are, the weight of the baggage, and the necessity for a dark room in every locality where it is decided to operate. Many ingenious attempts have been made to obviate the one, and provide a portable substitute for the other; hence the numerous portable cameras, portable tents, dark boxes, &c. &c., which solicit the suffrages of the ardent photographer. The use of dry plates, it was thought would reduce the baggage to a tolerable minimum; but the problem to be solved was—to operate with wet collodion in the open air, without tent, dark box, camera, or any of the baggage indispensable in the usual processes, and to obtain positive proofs in the space of two or three minutes, by means of apparatus reduced to dimensions so small, that, with every necessary, it might be carried to and fro without the least inconvenience. Mr. Claude Pallu claims the merit of having solved this problem.

Any important simplification of the photographer's apparatus necessarily entails a simplification in the manipulations to be performed, in the preparations necessary to be made, the suppression of most of the usual precautions to be taken, and consequently, the suppression of an important part of the operator's difficulties.

Thus photography would become "easy to everyone," but more especially so to the traveller and tourist, to those who admire and enjoy works of nature and art, and who desire to possess a simple instrument, at once portable and convenient, with which to operate quickly in broad daylight, and obtain by it positive proofs without the necessity of having recourse to the usual precautions, and this in whatever place the operator may chance to find himself, whether on mountain top or grassy plain, by hill or valley, running brook or flowing stream, without camera or anything that even the most captious would regard as an encumbrance.

This is a very attractive programme, and Mr. Claude Pallu conceives that he has performed it to the letter.

The apparatus he has contrived is of remarkable simplicity; it is easily managed, and with it focussing presents no difficulty, while the necessity for the operator's putting his head under a black cloth is obviated. This operation of focussing like all the others, is performed uncovered. The upper portion of this apparatus is formed by two sliding shutters, placed horizontally, and independently of each other, so that either can be removed without allowing light to enter the apparatus. This apparatus is a simple square box, to which the lens is fitted, and within which another box, carrying the ground glass, is made to slide, and which can be replaced at the proper time by the sensitized plate to obtain a picture.

The preparation of the sheets or plates to be sensitized is performed in a vertical gutta-percha bath, only having, at its upper part, a kind of longitudinal flap, the edges of which, folded internally, descend to within a certain distance of the bottom of the bath, and constitute a sort of channel or slide in which the sheet or plate is held vertically. A little piece of apparatus of the same height as the bath, called the *port-proof*, is made to cover or envelope the bath entirely, inside the top of which is a hook, by which the plate to be sensitized is held: a horizontal slide covers the lower portion, or bottom of the *port-proof*, which, when pushed over the bottom, hermetically closes this cover, and protects the plate within from any access of light.

When about to operate, the *port-proof* is adjusted to the apparatus carrying the lens; the first shutter of the box is now drawn out, and then the second, and immediately afterwards the slide at the bottom of the *port-proof* is drawn; the sensitized sheet or plate falls into the place it should occupy in the apparatus, into which it is guided and held by two grooves. The second shutter of the slide is immediately pushed back, the *port-proof* is raised, and the first plate pushed in; the apparatus is now hermetically closed. To operate, the lens is uncovered by raising, by means of a cord, a shutter placed in front, which slides in two grooves on the anterior face of the box. When the exposure is deemed sufficient, the shutter is allowed to fall again in front of the lens.

The picture obtained requires to be developed as usual; the box carrying the lens is reversed over a bath or dish similar to the first, containing the developing solution; the two shutters of the dark slide are withdrawn, and the plate falls of its own accord into the bath; the plate is next passed into the bath containing the fixing solution.

These successive operations are performed much quicker and easier than they can be described; indeed, the celerity with which the operator can act must be seen to be believed. The substitution of the little piece of apparatus called the *port-proof* for the camera is as ingenious as it is useful and advantageous, for it enables the operator not only to perform all the operations in broad daylight, but it also affords him the means of working without touching the silver bath or plate with the fingers: thus silver-stained hands are entirely avoided, which is no mean recommendation for lady amateurs and drawing-room operators.

To this array of advantages may be added still another; that of the facility it affords to every one desirous of obtaining photographic views, portraits, &c. The method is specially applicable to stereoscopic views. All the necessary apparatus may be contained within a space not exceeding eight cubic inches. It would seem impossible to reduce the photographer's encumbrances within a smaller compass. —*Science pour Tous.*

[We observe that the invention of M. Claude Pallu has just been made the subject of a patent in this country.—Ed.]

LUNAR PHOTOGRAHY.

BY SAMUEL FRY.*

The variation in size of the lunar negatives is much greater than would be supposed at first, but is of course owing to the moon's varying distance from the earth. I have here one plate of glass for comparison, a negative of the full moon taken at the period of perigee, or its nearest approach to the earth, and also one taken at apogee, its greatest distance. You will observe that the difference is very considerable, and in the after process of enlarging, where a stereoscopic combination is desired, the qualities of the two negatives are very different also, from the details of one being much more condensed than in the other, the enlargements will also differ to some small extent when brought up to the same size.

The principle of binocular vision is now well understood, and though the means taken are very different, yet the principles involved in taking a stereoscopic combination of the moon is precisely the same as employed in our binocular cameras for ordinary pictures. Though the moon is by far the nearest to us of any celestial body, yet such is her enormous distance, that even if simultaneous pictures could be taken of the satellite, with telescopes placed at the extreme diameter of the earth, 8,000 miles, the stereoscopic effect would be very slight; the method adopted is therefore to take advantage of the librations of the moon, and by obtaining pictures at different epochs, to afterwards unite them in the stereoscope. The libratory motion of the moon amounts in the maximum to $\frac{1}{8}$th, or rather more of the whole apparent lunar surface, but the period of time occupied in travelling from one extreme to the other is frequently very considerable, from the change or position being both in latitude and longitude a still longer period must elapse. By this I would imply that the distance of time is often considerable at which it is necessary to take pictures for a stereo combination, in order to have them at the same age of the moon, the average time occupied in travelling from one extreme of libration to the other is not more than 14 days; so that if we take, for example, 6 lunations, and a given age of the moon, say 60 hours after full, it will be found frequently that for several consecutive months the variation is so slight as to give no stereoscopic effect.

The most successful combination I succeeded in making was one in which the first negative was taken on November 23, 1858, and the other side of the combination on October 11, 1859, being an interval of nearly 11 months, and which, as may be seen in the stereoscope on the table, is sufficient to give powerful relief. I think it a point of great importance to display clearly in lunar photographs the details of the surface, as well as the general effect to be good. I have here the original negative of the right-hand picture of this combination, and it will be seen that the display of volcanic craters, mountain ranges, and even in many instances the interior cones of eruption are very striking. The period chosen for this picture is about 60 hours past the full, a time in my opinion very admirably suited to obtain good images, and when the solar light falls on the moon with sufficient obliquity to produce strong effect of light and shade, at the same time that it is almost, if not quite the nearest to full moon at which may be, reproduced at the gibbous edge, those exquisitely sharp cusps and volcanic craters. The time of exposure required to produce a good picture is of course different, according to circumstances, and the age of the moon, perhaps an average exposure at full, was about 3″. I have succeeded in taking a very fine negative in a single second, but under very favourable circumstances.

I have here a negative of the crescent moon, 4 days old, which required 45″ to be successful, and even then, but little detail is seen; the half moon required about 12″ on an average. I have invariably found that when the actinic power was highest I obtained the best pictures, as it is then there is least chance of any difference in speed between the telescope and the satellite.

I also exhibit here a series of negatives, of the eclipse of the moon in February last; on the left-hand picture, the penumbra may be clearly seen, just commencing, and on each of the others, further advanced till the last, beyond which I was unable to obtain any result, in consequence of the reddish copper-colour of the moon, which appeared to leave after this point, no photogenic action. The enlargement of the moon, which is before you, together with the print from the original negative, is from a negative taken on the evening of the eclipse before it commenced, and shows more of the moon, surface than at ordinary full moon, on account of the moon, earth, and sun, being at that time so nearly in a line, and thus allowing us to see very nearly the entire illuminated circle. However accurate, and however unremitting may be personal observation of the lunar surface, it must in many important respects yield to the photographic representation, by which any disturbance thereon cannot fail to be brought under our observation, and a series of pictures extending over a length of years, must of necessity be of the utmost value for future comparison.

* Read at the meeting of The London Photographic Society, on Tuesday, Jan. 8, 1861.

The enlargement, and subsequent uniting, stereoscopically of lunar pictures, is one of the most tedious and difficult operations the photographer can encounter; it is very unlikely that the two negatives are quite the same size, and still less likely that they have exactly similar photographic value, and yet, to be perfect, they must be made to intimately correspond in size and colour. My own practice, as being shortest ultimately, is to enlarge in the first place each negative separately, to about $1\frac{3}{4}$ inch, thus making a transmitted positive; these are again enlarged to 2 inches diameter, giving this time a negative, and the operation must be repeated until these two negatives have equal phtographic value. They are then mounted sterercoscopically on a stereoscopic plate, and fixed in front of an enlarging camera, in a slide made in such a manner that either image may at pleasure be drawn opposite the axis of a lens, placed midway between the negative and the ground glass.

Each side of the moon is copied separately on a piece of glass, and the transparent positives, thus obtained, are afterwards cut with a diamond to fit a mount, having a circular opening for each side; they are then bound in the same way as book-covers, and are complete: but the utmost care is necessary in mounting the two halves to obtain true sphericity in the stereoscope, as the slightest aberration causes apparent flattening of one part of the moon, and excessive convexity in another.

Proceedings of Societies.

City of Glasgow and West of Scotland Photographic Society.

Instead of the usual monthly meeting in January, this society resolved on holding a soirée and conversazione. It came off on Wednesday evening, the 9th, and, notwithstanding several untoward circumstances, was quite a success. The late hard frost had frozen the heating apparatus in the hall, in which the soirée was to have been held, and the only other available room was too small, and in no way so well suited as the one originally fixed on. The severe weather had also the effect of preventing a considerable number of members and friends from being present, from indisposition, particularly three members of council who had been active in making arrangements for the success of this, the first soirée of the society. These were Messrs. H. Wilson and A. Mactear, and the honorary secretary Mr. John Cramb, who had been appointed to deliver an address.

The chair was occupied by the president, John Kibble, Esq., who delivered an eloquent oration on Light. Mr. G. Gilmour gave an account detailing his Photographic experience, and what he saw during a tour on the Continent. Professor Taylor showed a number of photographs by the magic lantern on a 12-foot screen.

The hall and adjoining room were decorated with specimens of our art, contributed by members of council. Amongst them were prominent the numerous views by the President, one of which, 40 inches by 30 inches, was fitted up as a cosmorama, and seen through the magnificent lens with which it was taken looked truly grand. Mr. Kibble's monster camera, &c., with which these pictures are done, is much the largest in the world.

The large dimensions and other features of Mr. Kibble's photographs of the *Broomielaw*, will render a few particulars regarding them interesting. One of them is a glass positive, and is, we believe, the largest on record, and obtained for Mr. Kibble the Manchester medal. The other is in a paper print from a negative by the Taupenot process. The dimensions of the glass are, we believe, 44 inches by 30 inches; the weight of the negative is about 44 lbs. The lens with what these pictures were produced, was made by Ross, and cost £170. The diameter of the lens, clear of mounting, is 13 inches, and its focus, for parallel rays, 6 feet. The camera to which it is attached, was mounted on wheels and drawn by a horse.

Mr. White showed the stereoscopic effect by two magic lanterns very successfully; altogether, the meeting was a very happy one, whether from the fine speeches, fine pictures, or excellent music, or the presence of the ladies, or all combined, we know not, but have no doubt a similar combination will be again tried as the season comes round.

Experimenting in Meetings.—In our notice of a former meeting of the Glasgow and West of Scotland Photographic Society, we were not in possession of a somewhat novel and very interesting feature—the actual manipulation of several important chemical experiments. Mr. Macnab illustrated his paper by the following experiments: dissolving the metallic gold and making a solution fit for use in toning; throwing down silver from its solutions by various methods, as by means of metallic copper, by salt, by muriatic acid, and by caustic potash; producing nitrate of silver by means of nitric acid and washed oxide of silver, and explaining the method of crystallizing, a process in which he had had considerable successful experience. Mr. Macnab's example might, we think, be followed with advantage in other societies.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 16th January, 1861.

M. Augustus Testelin has investigated the subject of the constitution of the photographic image, and attempts to prove:—1st. That the formation of the photographic image is only one among many similar facts, which form a special class, regulated by constant laws, which are but a generalization of the principles of physics already applied in other cases. 2nd. That the photographic image is the result of a physical modification produced by light, and not the effect of a chemical change, as hitherto generally admitted. 3rd. That this physical modification, which results in making the latent image appear through contact with certain substances, is produced by electric polarity, which is due either to luminous radiations or to other causes capable of acting in a similar manner. I can hardly do justice to M. Testelin's researches without following the analytical course he has adopted, and in which he sums up in a very correct and interesting manner everything that is known respecting the physical and chemical action of light; at the same time electrical action is so often adduced as the cause of inexplicable phenomena, that even in this case, the demonstration being inconclusive, it must be received with caution, if not with doubt. At present, we are quite safe with the theory of the formation of the photographic image put forth by Messrs. Davanne and Girard. No other theory yet advanced is so satisfactory or so little liable to objection.

One of our most eminent photographers, M. Nadar, has experimented with Mr. Way's electric lamp in taking portraits at night, and succeeded admirably. The pictures are remarkably sharp, there is good half-tone, and the shadows are not opaque. It is difficult, nay scarcely possible, to distinguish portraits taken with this artificial light from those obtained in ordinary daylight. The invention of Mr. Way is so ingenious that it merits the warmest praise; the idea of turning the fluid mercury to account as an endless metallic wire, is truly a flash of genius, only paralled in brilliancy by the light itself. He has so successfully triumphed over many difficulties in perfecting his electric lamp, that it is not unreasonable to expect he will yet overcome the only one which yet remains, that arising from the volatilizing of the mercury, which creates a white atmosphere round the source of light, and soon envelopes it in a thick veil of mercury adherent to the sides of the glass of the lamp.

Messrs. Berthelot and Buignet have concluded some very important researches upon the phenomena that take place during the ripening of fruits, the principal result of which is, that in the grape the proportion of crystallizable sugar goes on constantly increasing in proportion as it approaches complete maturation. In their researches upon the nature, origin, and transformation of the saccharine matter in fruits, they come to the following conclusions:—1st. The sugar primarily formed in acid fruits is cane sugar, $C^{12}H^{11}O^{11}$, identical in its properties and rotary power with that extracted from the sugar-cane and from beetroot. 2nd. During the ripening of fruits, the sugar is submitted to a peculiar influence, and is gradually changed into reversed (*interverti*) sugar, $C^{12}H^{12}O^{12}$, identical in its properties and rotary power with that obtained by the action of acids or of glucose fragments upon cane sugar. 3rd. When we examine the saccharine matter at the epoch of complete maturation, we find it differently constituted in different fruits. It is in one case found to be composed of reversed sugar, pure and simple, as in the grape, fig, and currant; in other cases, it is a mixture in variable proportions of cane sugar and reversed sugar, as in the apricot, peach, plum, and pineapple. 4th. The ruling cause of these differences is not, as might be supposed, the acidity of the fruits. Experiments prove that the organic acids, on account of their relative proportion, their state of dilution, and the low temperature at which they act, have only a slight action in reversing the cane sugar with which they are associated. Besides, no relation exists between the acidity of the fruits and the alteration exhibited by their saccharine matter. The lemon, the acidity of which is excessive, presents more than one-fourth of its saccharine matter in the state of cane sugar, while the fig, which is scarcely acid at all, presents the whole of its sugar in the state of reversed sugar. So, also, we find 70 per cent. of cane sugar in the saccharine matter of the apricot, the peach, and the plum, while no trace of it exists in the grape and the cherry, our analysis detects much less acidity. 5th. The difference in the relative proportions of the two sugars is due to the influence of a nitrogenous material, performing the part of glucosic ferment, analogous to that recently extracted by Mr. Berthelot from beer yeast. By crushing the seeds of gooseberries, and treating them with cold water, we obtain a liquid which at a common temperature reverses the cane sugar contained in the juice of the fruit. 6th. The comparative influence of the acid and the ferment is rendered manifest by two parallel experiments made in the same fruit-juice: the one in which the ferment was precipitated by alcohol, the other in which the acid as neutralized by carbonate of lime. In the first the saccharine matter subsists for a very long time without sensible modification. In the second, on the contrary, it is completely transformed, even in the course of twenty-four hours. The same effect also results in experiments made with the fruit of the banana. At whatever period of vegetation we examine its juice, no trace of free acid can be found. But yet, in bananas artificially ripened, nearly two-thirds of the saccharine matter exists in the state of reversed sugar. 7th. So close an affinity exists between the cane sugar and the reversed sugar, that it is only with extreme difficulty one can be separated from the other. Thus, cane sugar loses its faculty of crystallizing when in presence of a very small portion of reversed sugar. So also, protoxide of lead, which acts very differently upon the two sugars in an isolated state, exercises the same kind of action upon each when they are mixed together. 8th. The abundance of starch found everywhere in the vegatable kingdom would lead us to suppose that it is the real source of the saccharine matter of fruits. Yet its presence in green fruits cannot be discovered, either by the microscope or by iodized water. On the other hand, the sugar to which starch gives rise in the artificial transformations to which it is submitted, is a dextrogenous glucose with a rotary power equal to +53, while it results from my experiments that that found in acid fruits is partially or totally reversed cane sugar—9th. There exists in green fruits a peculiar principle, endowed with the faculty of absorbing iodine with even greater energy than starch does, and of forming with this metalloid, a perfectly colourless compound. This principle is of an astringent nature, and appears to resemble tannin in most of its properties. Its analysis may be established with much greater facility than that of the saccharine matter itself. In experimenting at different stages of ripening, we recognise that its proportion progressively diminishes in proportion as the saccharine matter augments. 10th. In adding to the juice of green fruit as much iodine as it will absorb, we soon perceive a precipitate formed by the combination of iodine with the astringent matter. If we collect this precipitate and wash it with the greatest care, to free it from the soluble matters it may happen to retain, we find that it produces sugar under the influence of diluted acids at a suitable temperature. 11th. The sugar which the tannin of gall-nuts yields by the action of moderately concentrated sulphuric acid, is a dextrogenous glucose, having exactly the same rotary power as the glucose of starch. The sugar which the tannin of green fruits yields under the same conditions is also dextrogenous glucose, identical with starch-sugar. Under this relation tannin is no better than starch for a satisfactory theory of the origin of sugar in fruits. 12th. In green bananas we find at the same time much starch and much tannin; and the two principles diminish progressively and simultaneously, so that no trace of either one or the other is found in the same bananas ripened. The sugar found in their place is cane-sugar. 13th. There exists, therefore, a very essential difference between the processes of art and the processes of nature, with respect to the transformation of tannin or starch into sugar. There is also a very great difference between the saccharine matter of fruits, according as it is produced under the action of vegetative forces, or out of their influence. Experiments show that the sugar which continues to be formed in the bananas after they are gathered from the tree, is no longer cane-sugar, but reversed sugar.

LONDON PHOTOGRAPHIC SOCIETY.

"WHO'S TO BELL THE CAT?"

Mr. Editor,—I was pleased to read the letter of "Progress" in last week's News. I used to be a member, but dropped it, for the meetings were so dull and heavy, and the "Journal" such a prosy affair; so I joined what "Progress" calls a suburban one, and I like it a great deal better.

We have our monthly meetings, and read our papers, and gossip and chat together, talk about all the new discoveries and re-discoveries, and are very merry and happy, and get a deal of information. It is very different to the dead-and-alive affairs of the old society, where everything used to be as dull as an old country church, and as uncomfortable as a court of justice, and especially when I saw the venerable Judge Pollock sitting on the raised seat before me, I always felt as if I were about to be tried for my life.

"Progress" thinks all the evil lies in the council; if I could whisper a word in his ear, I'd say, "the council is all *bosh!*" I wish he'd attend one of *our* meetings, and see how *we* do it. We are our own council, we put our active men on the committee, and our president is the most energetic and intelligent of us all. We have our journal, not once a month, but every fortnight, and during the year get a splendid photograph, and all this for half the money the *Grandmother* Society, as somebody calls it, charges. So I think it time that the old lady was woke up a bit. We have no grand and solemn self-elected body, sitting in the front seats to manage our affairs for us, and put down anybody who ventures to disturb the order of their proceedings.

This grand council is like the old man round Sindbad the Sailor's neck, it will strangle the society if it don't mind; and if "Progress" can induce the members to shake it off, so much the better for them, but "*Who's to bell the Cat?*"

A Former Member.

ON COAGULATED ALBUMEN, &c.

Jan. 7th, 1861.

Dear Sir,—At the meeting of the London Photographic Society, held on the 4th of December last, I find it reported that Dr. Riley asked,—"Could Mr. Hardwich inform him how it was that the sensitiveness as well as intensity of the plate was increased by the coagulation of the albumen by hot water. Sulphate of iron, acetic acid, and alcohol would produce a similar effect, but not to the same extent." In reply, Mr. Hardwich said,—"that the hot water might perhaps wash away the soluble chlorides and phosphates from the albumen. That might account for the fact, that the coating of albumen, *coagulated by dry heat*, was not so sensitive." Previous to this question of Dr. Ryley's, Mr. Sebastian Davis is reported to have said, "He prepared plates, and *washed away all the free nitrate*, and coated them with albumen. He then placed the plates in an atmosphere of dry air at 180 degrees, *to coagulate the albumen*; on exposing the plates he found they possessed little or no sensibility to the action of light. This would appear to *contradict* the theory, that it was only necessary to coagulate the albumen to produce sensibility. He then dipped some plates in boiling water instead of exposing them to hot air, so as to wash them at the same time. The plates so treated were far more sensitive."

I wish, sir, to draw your attention to the erroneous idea respecting the coagulation of albumen, which the above conversation displays. I will here state the chief characteristics of albumen. The white of an egg is not *pure* albumen, as it contains also, a small quantity of mucus, soda, and sulphur; but as we do not know any method of separating these substances from the albumen without altering its properties, we are forced to treat it in combination with them. Albumen in its natural state, *i.e.*, uncoagulated, *dissolves readily in water;* when dried spontaneously, or in a low heat, it becomes a brittle, transparent substance somewhat resembling gum arabic, and loses about four-fifths of its weight, but *is still soluble in water*. When albumen is heated (*heated* mind, *not dried*) to the temperature of 165°, it *coagulates* into a white sold mass; not only its appearance, but its properties become entirely changed by coagulation, as it is *no longer soluble in water*, either hot or cold, and unlike *dried* albumen, *it has precisely the same weight and bulk that it had when fluid*. Albumen is also coagulated by acids, but in a lesser degree, and several of them have the property of dissolving it when assisted by heat; alcohol and ether will likewise coagulate it, in both of which it is insoluble.

If, sir, the sensitiveness of the plates in the processes where collodion and albumen are used in conjunction, is in any way dependent upon the coagulation of the albumen, it seems but common sense to suppose that the more complete it can be rendered, the greater will be the sensitiveness (all other things remaining the same); at all events, if any amount of coagulation, however slight, will increase the sensitiveness of the plate, the mere *drying* the albumen cannot reasonably be expected to produce the same result, as dried albumen and coagulated albumen, have not any properties in common. Why then, should Mr. Davis say that the non-sensitiveness of his plates with *dried* albumen, appeared to contradict the theory that *coagulation* of the albumen is necessary for their sensitiveness; and why should Mr. Hardwich speak of *coagulation by dry heat*, but for the simple reason that they confound drying with coagulation. The unimportant discussion, as to whether the sensitiveness is due to structural or chemical change in the albumen, could only have arisen from such erroneous ideas, as, in our present state of chemical knowledge, it is impossible to tell from *which* cause it arises, as *both* the structural and chemical properties of albumen are changed by coagulation.

If the *whole* of the free nitrate is washed out of the collodion previous to coating with albumen (as in Mr. Davis's experiment), there is nothing left to render the albumen sensitive, and it, therefore, when dried, will interpose a non-sensitive film between the collodion and the action of light; it thus must necessarily either render the plate wholly insensitive, or diminish its sensitiveness in proportion to the thickness of the albumen film; if, instead of drying the albumen, the plate is dipped in hot water, the hot water probably dissolves some of the nitrate contained in the collodion, which combining with the albumen, renders it sensitive.

It seems also, that very erroneous ideas exist as to the *necessity* for washing out the free nitrate, and for using a second bath, such bath being but a necessary consequence of the washing, as the bath only *restores* to the plate what it had been deprived of by the washing; in proof of this, if the sensitized plate is *not* washed and thus the whole of the free nitrate allowed to remain, *no second bath is required;* a friend of mine has thus prepared his plates *for several years*.

Why does the Fothergill process dispense with the second bath? simply because the free nitrate is not *wholly* washed away, but enough is left after the slight washing in the "diluting" tray to combine with the albumen. The Taupenot process *requires* a second sensitizing bath: but *why* does it do so? because it is in fact *two distinct and separate processes*, the one superposed in the other; we first have an iodized collodion rendered sensitive, and thus complete in itself; *upon this*, we place an iodized albumen, and thereby wholly or partly destroy the sensitiveness of the previous collodion, and having done so, we must of course sensitize the upper or albumen film: thus having *two* sensitive surfaces, one *under the other*, the lower one of no use except to complicate the process, as the image is on the albumen and not on the collodion.

With respect to Petschler and Mann's process, I think that the common-sense explanation of it is, the chlorided albumen film being *insensitive*, the washing it away exposes the sensitive collodion film under it to the action of the light, and as a necessary consequence, no second bath is requisite; if any chlorided albumen, is allowed to remain there must necessarily occur patches of irregular sensitiveness, in proportion to the thickness of the film not washed away; *the image cannot therefore be anywhere else than on the collodion or sensitive film*. The albumen serves no other purpose, than to protect the collodion from the action of the light; and methinks this modification might have been arrived at long ago, by anyone who had taken the trouble to reason as to why the second bath in Taupenot's process is necessary.

Although the subject is anything but exhausted, I fear you will think my letter already too long, and therefore, congratulating you on the completion of your fourth volume, I remain, dear sir, your sincere well-wisher, G. P.

PHOTOGRAPHING ON WOOD.

16, *St. Augustine Road, Camden Square, N.W.*
15*th July*, 1861.

Sir,—In the report of the meeting of the Photographic Society, in your number of the 11th instant, the subject of photographing on wood forms a very important feature. There is, however, one omission which, if not supplied, is calculated to do me great injury—viz., that although photographing on wood has been attempted by various persons, it has only become practicable in my hands, whereas; from the report of the meeting, it would appear that M. Joubert was the successful experimentalist. M. Joubert was, perhaps, not then aware that the designs I engraved for the *Lyra Germanica* were engraved on blocks on which they had been photographed by myself. It is true that those designs were printed on blocks by M. Joubert, but from the imperfect nature of his process, they could not be engraved, and had to be erased to give place to the same design printed by my process. This fact can be attested by M. Leighton, for whom I photographed and engraved these designs.

Trusting to your well-known sense of justice to give me the opportunity of establishing my just claim to the title of being the first to carry this process to a successful issue.—I remain, sir, your obedient servant, Thomas Bolton.

[We feel quite assured that M. Joubert was not aware that Mr. Bolton had produced the photographs on the wood from which the engravings were produced. From the appearance of the uncut block exhibited he had every reason to believe it was the one he had himself done, a conviction which the memory of Mr. Warren de la Rue and ourselves confirmed him in. We feel assured he would be the last person to make a claim to which he was not legitimately entitled. If the process of Mr. Bolton is not a secret, we shall feel interested in receiving some particulars for publication.—Ed.]

Meeting of the Photographic Society.—Dallmeyer's Triplet Lens, &c.

Sir,—It appeared to the chairman that the remarks I was addressing to the meeting last night would originate a discussion which might encroach upon the time that would be required by Mr. Fry's paper. It was for this reason I gave way; I should, however, be glad to take this means of putting myself right with the meeting. Prior to the 4th December last, I gave notice of my intention to make some remarks at the meeting of that date, upon Mr. Dallmeyer's triplet lens; and if the discussion upon Mr. Thomas's paper had not occupied the time it did, I should have done so. I maintain, therefore, that my notice held good for the meeting of last night; and, as I yesterday reminded Dr. Diamond of my claim, I think it will be seen that my proceedings were quite in order. I mention this, because, at the conclusion of the meeting, I was told that what I was doing was irregular, and that the chairman was justified in stopping me. To those who think so I address the foregoing explanation.

As our next meeting will probably be entirely occupied with the business of the annual meeting, I will now ask permission to use the News for the remarks I desired to make last night.

There is no question that Mr. Dallmeyer's triplet lens has its peculiar advantages, and that it provides against certain defects of certain lenses; but I should like to be convinced that it fulfils some other conditions which Mr. Dallmeyer says it does. I do not mean to say that it does not; but I confess that I do not exactly understand what is meant by the assertion that it is "quicker-acting than the orthographic or single combination lenses." Quicker-acting is so peculiar a term, that I ask whether it is intended by it (the size and the definition of the resulting pictures being equal) that the triplet lens will produce its pictures in less time than the orthographic or single lens. My own experiments give a result the very reverse of this; but perhaps I do not understand Mr. Dallmeyer's mode of comparison. I must, however, insist that no comparison can be just, *which does not include perfect equality in the size and definition of the pictures produced.*

I cannot help calling attention to the fact that Mr. Dallmeyer's assertion is not made concerning the Petzval combinations generally, but that, for his comparison with lenses of that principle, he has singled out the orthographic, which is the lens of Mr. Ross. It is really, therefore, but reasonably fair that there should be no ambiguity about the terms or the manner of the comparison made. I will merely add that if it should lay in Mr. Dallmeyer's power to demonstrate the accuracy of his assertions, he will have no cause to regret the remarks I have made here; but, on the other hand, I think that if one or other of those assertions fail to be verified, it will be admitted that the notice I have taken of them is completely justified.

Allow me now to take advantage of this opportunity of addressing you, to call attention to an advertisement in a recent number of the Photographic News, in which a camera is stated to be "the only camera that will stand the climate of India."

Now there is no question that in an advertisement every one has a right to speak of whatever he may produce new and good in the most favourable manner possible; but no one is justified in an assertion which all who are acquainted with what has been done by photography in India and elsewhere know to be untrue, and which can only be hazarded to catch the ignorant.

Time and experience will most assuredly supply the necessary corrective; I must ask you, however, to allow me at once, in my own name, and on behalf of the several other manufacturers whose apparatus has been, and is, most successfully employed in India, to protest against this upstart and unfounded assertion.

Vernon Heath.

19, *Bloomsbury Street, Jan.* 16, 1861.

Sir,—I am sure you will favour me with the insertion of the inclosed letter in answer to Mr. Heath's remark, contained in your report of the last meeting of the London Photographic Society.

At our last meeting, Mr. Heath (Murray and Heath, opticians) attempted to ask some questions apparently respecting a statement put forth in my "advertisement" to the effect that the "Triple Achromatic Lens" constructed by me is quicker-acting than the "Orthographic or Single Combination View Lenses," observing that this had not been verified in "his" experience.

The Chairman here interrupted the speaker, and pronounced the subject irrelevant.

Since, however, the question has been asked, I am sure you will allow me to give the answer.

First, the "Triple Achromatic Lens" is quicker-acting than the "Orthographic," because the relative intensities or quickness of two lenses (having the same number of reflecting surfaces) are in direct proportion as the squares of their apertures, and inversely as the squares of their foci. Now the focal length of the Orthographic, for a given size plate, and with the same aperture, is *longer* than that of my "Triple" lens in the proportions of 10 : 9, and therefore their intensities will be expressed by $1^2 : 9^2 :: 1^2 : 10^2$, or as 81 : 100; in round numbers, as 4 : 5; giving my lens the advantage to the amount of $\frac{1}{5}$.

My reason for making the comparison with the "Orthographic" is owing to the fact that, having assisted my late father-in-law (Mr. Andrew Ross) in its construction, it will readily be conceded that I am intimately acquainted with all its properties.

Secondly, the "Triple Achromatic Lens" is quicker-acting than the Single Combination View Lens, because, for the same size picture, and with equal diameters of stops, its focal length is less in the proportion of 10 : 9·4; therefore, according to the above rule, its intensity in round numbers is greater by $\frac{1}{8}$.

The loss of light, as occasioned by the greater number of reflecting surfaces in the "Triple," is compensated for by the circumstance that, although stops of equal diameters are employed in both cases, yet the size of the pencils of light, as transmitted by the two lenses, is by no means the same: for in the case of the Single View Lens the stop is situated "before" the lens, and therefore limits the diameter of the several pencils before refraction; but in the case of the "Triple" the stop is situated "behind" the front positive combination, where the rays are already converging, and therefore the pencil of light received and transmitted is considerably larger than the diameter of the stop.

I may observe, that what has been advanced above has also been confirmed in the experience of numerous professional photographers, and it was only after that confirmation had been obtained that the announcement was made in my advertisement.

In regard to other good qualities possessed by my new lens, such as perfection of definition, flatness of field, perfect straightness of marginal lines, &c., Mr. Heath does not appear to question; and since photographers and the public generally are already well acquainted with the "Triple Achromatic Lens" and its merits, I will not trespass any further upon your valuable space.

J. H. Dallmeyer.

Apparatus.

Instantaneous Shutter.

A shutter for rapid or instantaneous exposures, with a bi-lens stereoscopic camera, was exhibited by Mr. Dallmeyer, at the last meeting of the Photographic Society. It consists, in its simplest form, of a shallow box of mahogany, made to fit on to the hoods of the lenses, and may be added or removed at pleasure. The lip is moved up or down by a brass milled head, attached to a rod which forms the hinge. In the letter accompanying it, Mr. Dallmeyer said:—

"It needs no description. I will only mention that on throwing the centre of motion somewhat backwards, the lid is always *certain* to close, even if the camera be inclined *downwards* from 5 to 10 degrees; and for the same reason also, when turning the lid up, it *remains* in that position, and thus allows for focussing, or a more prolonged exposure. Also, since by the action of the shutter the foreground receives the greater exposure, it favours the obtaining of a more natural sky in the picture.

"The movement is, perhaps, not quite rapid enough for waves and the like, but for the ordinary *quasi* instantaneous views (appropriately so-called by Mr. Lake Price), it is found quite sufficient."

Where it is intended to be used with cameras having an arrangement for separating the lenses to different distances, it is made entirely of brass, and consists of two tubes moving on a rod to fit the hoods of the lenses.

Whilst referring to Mr. Dallmeyer's new instantaneous stereoscopic lenses, for especial use with which this shutter was contrived, we may take occasion to remark that we have used one of them, for various purposes, with the most complete satisfaction during the last few months, and have found it exceedingly rapid, covering a large angle with perfect definition throughout, and free from distortion. From the unsuitability of the season we have not had an opportunity of trying it for landscapes, but for copying and enlarging we have found it everything we could desire.

Talk in the Studio.

Photography and History. One of the most interesting of all our historical records, the celebrated Tapestry of Bayeux has been reproduced by photography. The photographs, executed by Herr Albert of Munich are just published by Messrs. Bell and Daldy.

A New School of Art is to be formed at Hertford.

The French Emperor and Photography.—His Imperial Majesty the Emperor of the French has forwarded to Mr. Maxwell Lyle a magnificent pin, mounted with diamonds and rubies, in recognition of an album of his marvellous views of the Pyrennees which he had forwarded to the Emperor. The gift was accompanied by some very flattering remarks, to the effect that the more he saw of the beautiful photographs of Mr. Lyte, the more he admired them, and that his congratulations and thanks were addressed, not only to the photographer of works of rare merit, but to a chemist whose discoveries his Majesty knew how to appreciate.

Photographic Piracy.—A deputation of publishers, consisting of Mr. Graves, Mr. Gambert, Mr. Fores, Mr. Lloyd, and Mr. White, waited upon Sir George Cornwall Lewis, at the Home Office, for the purpose of obtaining facilities for stopping at the Custom House, piracies of English engravings; and also a more speedy and less expensive remedy against *photographers* and other producers and sellers of pirated copies of English copyright engravings.—*Times.*

Photography and Fluorescence.—At a recent monthly meeting of the members of the Royal Institution, Professor Faraday exhibited photographs of fluorescent substances, which had been prepared by Dr. J. H. Gladstone. He reminded the members present of experiments they had seen in that theatre, showing that such bodies as di-sulphate of quinine emit a beautiful blueish light when they are exposed to the most refrangibile of the chemical rays of the spectrum, and are also phosphorescent. Several of these are white or colourless to look at, under ordinary circumstances; but it had occurred to Dr. Gladstone that, on account of their lowering the refrangibility of the chemical rays, they would, perhaps, not produce so great a photographic effect as other white substances. He had, therefore, drawn various devices in quinine salt, esculine from horse-chesnut bark, and other fluorescent substances on white paper, and had had the apparently white sheet photographed. The devices all came out dark, as was seen by the specimens exhibited, and, more than that, on a sheet of paper coloured blue with cobalt, were fixed letters, cut out of white, and steeped in the fluorescent solutions above mentioned. When this sheet was photographed, the blue paper was bound to have a much greater chemical effect than the white letters, which, therefore, appeared in the positive photograph dark, on a light ground.

Conceits of the Photographic Gallery.— The editor of the *San Francisco Mirror* remarks—We have never failed to derive amusement from studying the pictorial show-cases of the daguerrean artists. The sublimity of affectation is exhibited there, despite the efforts of the artists who can seldom keep sitters from "making up faces." Very few are content to appear in the pictures as they do in life, but manage to fix up in some absurd or unnatural attitude, which makes the spectators laugh. Some gentlemen affect the literary, and with this intent borrow one of the artist's books to give a show of attachment to letters; others group together, with arms locked, hats on one side of each head, affecting "gentlemen roughs," and others smile in a peculiarly saccharine manner, which, when ambrotyped or photographed, gives the face something of the expression said to belong to dead people found in the poisoned Valley of Sardis. Ladies, too, are not without affectation in attitude, and spoil their pictures by efforts to look unnaturally agreeable. It must be rare amusement for husbands in possession of *impulsive* wives to pass from the nursery, where the irate mother is "sloshin' about" among disorderly young ones, representing the "enraged parient," and find the same face limned on the show-case in all the mildness, suavity, and smiling sweetness of a "swamp angel." But the most pitiable of all sights is to observe that a person on the downhill of life has tried to look young and "peart," instead of manfully or womanly owning up to the full measure of years. Study the galleries attentively, and observe a great diversity of queer conceits and absurd attitudes.

To Correspondents.

W. H. Warner.—The term "transparent yellow" probably refers to gamboge; but we cannot say with any certainty unless you can refer us to the article in which it occurs. The quantity of salt to be added to the water in which prints are washed before immersing in the alkaline gold bath, is not important. With the length of washing you name it need not be used at all. We generally wash in two or three changes of common water for about a quarter of an hour in each.

J. C. A.—See pp. 56 and 372 Vol. iv. of the Photographic News.

S. V. W.—Steam water, carefully collected in a clean vessel, will generally answer the purpose of distilled water. Nitrate of silver is the usual test for the presence of chlorides and carbonates, and produces turbidity.

F. C. Camm.—The causes of the film cracking on drying are various. They sometimes proceed from a faulty collodion; very often from an imperfectly cleaned plate; and sometimes from over-development of an under exposed plate.

R. J.—We gave the formula on the statement of an experienced colourist, and are not familiar with its action ourselves. In our own practice we have used the ordinary megilp made as you describe, with drying oil and mastic varnish, and, used with care, find it answer the purpose satisfactorily. Used in excess, it will, of course, turn yellow and horny. Paper positives can be obtained from a negative by means of an enlarging camera without a condenser. A longer exposure will be required, and printing by development must be adopted.

W. L.—The albumen is best used tolerably fresh; but a slight amount of smell is not a serious objection if it be not decomposed. 2. Use a little brush and a strong solution of soda and water. 3. We cannot tell you whether the preparation to which you refer will answer its purpose or not. The addition of a bromide will often partially restore or increase the sensitiveness of an old iodized collodion which has grown slow by age; and it will assuredly, if added at first, prevent the loss of sensitiveness.

W. S.—White or blue calico is suitable for blinds in a glass room. 2. You can easily prepare oxide of silver by the directions you find in the News; or you may purchase it ready prepared. We have had no personal experience of the lenses you name; but have seen some good pictures said to be produced by them.

C. Eades.—We are not in possession of the information, but will enquire. There is some mistake in forwarding the recipe for paste blacking. We do not remember an enquiry under the signature of "Crispin."

Neg. Blister.—You are by no means singular in your misfortune; blisters in varnished negatives have been a prevalent evil of late. One of the chief causes, has been we apprehend, the unprecedentedly damp season. Imperfect washing after fixation, materially aids in producing this effect The ridges you describe are generally caused by, and contain moisture, which is probably due to some soluble salts left in the film. You will find the subject fully discussed in the Photographic News for Dec. 14th and 21st. 2. Your bath probably contains an excess of organic matter. Expose in a shallow vessel to evaporate the accumulation of ether and alcohol, and to light to reduce the organic matter. Neutralize excess of acid with oxide of silver, not with carbonate of soda, and finally filter. We have found this method restore such a bath as you describe to perfect working condition. It is somewhat difficult to say exactly what substances a bath which has been long in use contains, unless you know the exact composition of all the collodion which has been used with it. *Pure* gutta percha has no effect on nitrate of silver, but some articles sold as gutta percha are contaminated with a variety of substances. You may reduce the amount of acid in your developer in cold weather, but it will not be wise to omit it entirely.

Mr. F. Richards.—We have a letter for this correspondent if he will forward his address. Two or three correspondents have asked for a brief and precise statement of the formula for the albumen process which he uses, as referred to in his recent communication recommending its adoption.

Magic Lanterns.—A reader asks our recent correspondent, who speaks of having made a respectable magic lantern by the aid of his quarter-plate portrait lens, to communicate his experience as to the best mode of setting about such an undertaking. Several of our correspondents have experimented in this direction, who will perhaps aid our enquirer.

Leo. Daft.—Your letter will appear in our next. We shall be glad to receive further particulars.

A Disappointed Visitor.—We cannot agree with you that there is any declension in manipulatory or artistic skill manifested in the Exhibition. There is an absence of many things we should have liked to see present, but most of the things exhibited are really good. If you cannot see the excellence, remember, "the eye only sees that it brings with it the power to see." Borrow from the library of some of your juvenile friends an interesting little work by Mrs. Barbauld and Dr Aikin, entitled "Evenings at Home," and read the article, "Eyes and No Eyes."

G. G.—We will give some hints on French polishing shortly.

J. M.—We are much gratified with your expression of good opinion, because it shows such an accurate appreciation of our aim. Mr Atkinson of Liverpool is an agent for many American goods; but whether for the lenses you mention we cannot say. Many of Harrison's lenses are very good; but there are many equally good makers in this country, and some, we should scarcely hesitate in saying, who are decidedly superior. We have worked with Harrison's lenses and know them.

A few Amateur Subscribers, Zaffar, E. A. H., and others in our next.

A. L. Z.—See pp. 56 and 375 of vol. 4 of the Photographic News.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32 Paternoster Row, London.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St, Martin's-le-Grand.

THE PHOTOGRAPHIC NEWS.

VOL. V. No. 125.—January 25, 1861.

THE EXHIBITION OF ARCHITECTURAL PHOTOGRAPHIC ASSOCIATION.

THE Exhibition of the Architectural Photographic Association is this year incomparably the best yet held under its auspices, and is decidedly better in relation to its scope, than that in connection with the Photographic Society, regarded as an exhibition of the general powers of the art. Many of the pictures here exhibited leave absolutely nothing to desire in connection with the perfect rendering of architectural subjects. How far it is true that the depicting of architectural subjects is the most legitimate *metier* of the photographer as some hold, we will not say; but this, we think, will, by most persons competent to judge, be readily admitted, that higher perfection has been attained in this branch of photography than in any other.

Taking incomparably the first rank here, we think, are the productions of Francis Bedford. And, before proceeding further, we must enter our indignant protest against an opinion we have heard more than once expressed, and which we find declared in a very matter-of-course way in one of the morning papers, namely, that the productions of English photographers are vastly inferior to those of their continental compeers, the French and Italian photographers, and that the works of Bisson show "signs of greater judgment and artistic feeling than can be perceived in the works of our best men." We most emphatically demur to this opinion: recognising heartily all the merits of the continental artists; especially admiring the magnificent photographs sent by Bisson to this Exhibition, which certainly possess the perfection of literal or mechanical photography; we nevertheless unhesitatingly express our conviction that in all points, except size, they are equalled by the pictures of many English photographers, and that in the exhibition of artistic feeling, they are entirely surpassed by the pictures of Francis Bedford.

Architectural pictures may appear, and to a certain extent are, difficult subjects in which to display much artistic feeling. The most perfect literal transcript of the building, with every detail made out, presenting indeed in all respects photographic perfection, would appear necessarily to constitute the best architectural picture; and this may to a certain extent be true. But there is in many of Bedford's photographs here exhibited, such a display of fine taste and feeling in the selection of view, and still more especially in the choice of light and circumstances, as give to his productions a high pictorial value as works of art, entirely beyond their merit as architectural studies. Amongst the pictures of Bristol Cathedral, No. 229, "Entrance to the Chapter House;" No. 231, "The North Aisle;" and No. 228, "The Archway to College Green," are especially worthy of attention. Amongst the views of Wells Cathedral are some especial gems, amongst which No. 251, "The West Front;" Nos. 253 and 254, "The North Porch;" No. 256, "The South Aisle," and some others in the same series will excite admiration. Some of the most exquisite things, exhibited by Mr. Bedford, are the photographs from the interior of St. Paul's of the fine carvings of Grinlin Gibbons: these will well repay the most careful examination. Some views of the Cathedral at Canterbury, and the Rivaulx Abbey, are also very fine.

Perhaps the largest exhibitor, in every sense of the word, both as to number and demensions of his productions, is M. Bisson, who contributes not less than sixty-five specimens, the majority of which are of very large size, and, a we have before said, of undoubted excellence. "The Entrance to the Imperial Library of the Louvre," No. 5, is a magnificent specimen of photography, as are the various views of Rheims and Rouen Cathedrals. Notwithstanding the large size of many of these, which are not less, we imagine, than twenty-fonr inches square, they are free from distortion, and exhibit perfect definition to the corners of the plates. Taken in full sunlight, they are brilliant and vigourous, whilst there is not the smallest patch of light without detail, nor of black shadow without drawing. The shadows indeed are exquisitely transparent, the eye being carried by tender gradations into their deepest gloom. There is moreover a relief and a vigour combined with the utmost microscopic delicacy of detail, rarely met with, which give to these specimens of the best period of Gothic architecture —we are especially referring to the Rouen pictures—an especial value to the connoisseur. Almost all Bisson's pictures present very excellent photography, but there are some in which the distortion produced by the lens, or the misuse of it, is very offensive. No. 53, "The Great Clock, S. Ouen Cathedral," is a glaring example of what, using a solecism, has been called, "converging perpendiculars." We are somewhat surprised to find that Bisson, whose very large pictures are so perfect in every respect, should exhibit a number of moderate-sized ones so strikingly faulty.

M. Legrey exhibits a few fine and large specimens of Notre Dame, which will receive much attention. No. 79 is a very noticeable picture, not only as an excellent photograph, but from the extraordinarily grotesque character of its subject, which forms part of a carving of the last judgment, in the old Parisian Cathedral.

Messrs. Cundall and Downes have a goodly show of specimens here, many of which are exceedingly happy. The series of Winchester Cathedral please us best, and present some magnificent photography. Mr. Dallmeyer's triplet lens has rendered a good account of itself here, giving absolute freedom from distortion under the most trying circumstances. We must not omit to notice an exquisite little vignette, No. 103, "A View of St. Paul's from the River." The usual explanation is given for vignetting this picture, that the outside was imperfect. We would very much rather believe it was the result of deliberate intention, for it is a case where the sacrifice of part of the negative has produced a real picture, which the full introduction of details might have marred.

Mr. Fenton exhibits a large number of specimens, many of which are very fine, although there is more or less a tendency to the fault of which we have before spoken. "The North Porch, Southwell Abbey," No. 221, is an excellent picture, as is also 224, "Harewood House, from the Parterre."

We have not space here to notice the exquisite Egyptian photographs of Frith, nor the pictures of Moens, Captain Austen, Church, Mudd, Dolamore and Bullock, and others; but must return to them on another occasion.

An interesting feature in connection with this Exhibition is the delivery of lectures, every Tuesday evening, on subjects connected with the various photographs exhibited. The first lecture, delivered last Tuesday evening, was on the Egyptian photographs, by Joseph Bonomi, Esq., who with much lucidity traced the dim antiquity and consequent interest of the subjects of many of the pictures, and the great historic value of the photographs as authentic records of these relics of architecture, which extend back almost into the night of time.

THE PHOTOGRAPHIC EXHIBITION.

Second Notice.

A second examination of the photographs at the Exhibition, brings under our notice a series of specimens which we had at first passed by somewhat hastily, without discovering the amount of real beauty and excellence they possess; we refer to the pictures exhibited by Mr. Vernon Heath, consisting chiefly of views at Endsleigh, the seat of his Grace the Duke of Bedford. The whole of this series are full of picturesque beauty, and are at the same time fine examples of very perfect photography. The series consists of fourteen pictures, each, as we have said, possessing beauties of its own, but of this number, those which please us best are No. 4, in frame 213, "In Dairy Dell," and No. 4, in frame 230, "The Gardener's Cottage." The latter is a most charming vignetted picture; the cottage is embowered in flowers and foliage, and surrounded by trees. We heard it explained that this vignetting was rendered necessary by the imperfections from the movement of the foliage, &c. We are unwilling, for the sake of Mr. Heath's taste, to accept such an explanation. We would much rather believe that he willingly sacrificed some trifle in the size of his picture, to the production of the exquisitely artistic effect here exhibited. The general feeling pervading these photographs is very similar to that which characterises Mr. Mudd's, to which they are only second. Great taste has been displayed in the selection of the views, and the delicate tender mode of treatment does entire justice to the views selected; full of gradation and half-tone, they are at the same time brilliant and forcible pictures.

A series of large and vigorous photographs from the Elgin Marbles, executed by Caldesi, Blandford, and Co., afford a satisfactory illustration of the value of photography in an educational point of view. No drawings made by the hand of man could possibly possess a tithe of the truth and value, to the student without access to the originals, which belongs to these photographs. Of equal merit, and even more of picturesque value, inasmuch as they render perfect subjects rather than fragments, are the large photographs of "The Seasons," executed from Thorwalsden's bas-reliefs, and exhibited by the London Stereoscopic Company.

Those of the visitors to this exhibition who saw Mr. Hickes' picture of "The Post-office; One Minute to Six o'clock," shown at the last Exhibition of the Royal Academy, will be delighted with the photographic copy by Messrs. Cundall and Downes. Notwithstanding the difficulties presented to the photographer by the amount of brilliant colour in the original picture, much of the vigour and life of the painting is preserved. Perhaps the most interesting picture amongst the class of reproductions is Doviziclli's photograph of Guido's Aurora, which is on a very large scale, and exquisite in its truthful rendering of the original painting. Much as we are indisposed to admit the conclusions of the critic of *The Times* on many subjects connected with photography, we cannot forbear quoting his remarks on this subject, "How inexpressibly inferior to the photograph is the best of the many engravings of Guido's masterpiece! And yet it has been fortunate in its engravers. But take the best in that sort, and we maintain that the best imitation which the burin of even a Strange, an Anderloni, or Longhi can produce, would be poor and dead to such a version as this of the great work of the Rospigliosi Palace. We say this with profound conviction, not unaware of the charges of heresy that such a profession of faith may expose us to from certain schools of connoisseurship. But were we sure that photographs of pictures would last, we are not sure that we should not be content to see engraving numbered among the extinct arts." This much from a critic who has felt it necessary at the outset to guard himself very carefully from being supposed to recognise photography as a fine art, and has expressed his profound satisfaction that "the domain where photography ends should be so sharply and certainly fenced off as it is from where art begins," is gratifying homage to the power of our art. With all our warm love for, and faith in, photography, we should have hesitated to express such an opinion as is thus uncompromisingly uttered, if not by an antagonistic critic, yet by one, whom we, as photographers, would regard as at least an "outsider."

A further examination of some of Mr. Fenton's pictures is more satisfactory than the first. In the series of photographs of Furness Abbey he has been very happy. No. 22, "The Nave, from the East," is a magnificent picture, and quite stereoscopic in its relief and vigour, whilst the effect of light and shadow is very beautiful. One very peculiar effect of the lowness of tone, of which we last week complained as pervading Mr. Fenton's photographs, is the twilight effect which seems to pervade the landscapes: almost every picture suggests the idea that it was taken just at the commencement of the "gloaming." The effect aimed at is manifestly that of softness, and the rendering of detail in all the lights and perfect drawing in all the shadows; but the fact is, that in many of the pictures there are absolutely no lights at all, and the observer is tantalized by desire to seize a pencil and touch in a few vigorous lights to give brilliancy and life to the picture. In many of the prints there is also sufficient want of transparency in the shadows, to indicate that the negative was just verging on fogging; and suggest that a very new collodion in its highest state of sensitiveness was used, and excited in a neutral bath, when everything was in a state of trembling equilibrium between perfect results and absolute fogging. Mr. Fenton's productions have so long been regarded as standards of excellence amongst photographers, that whilst fully recognising all their real beauties, we feel the more imperatively called upon to point out their faults, which might find imitators. No. 143, "The Terrace, &c., Harewood," is one of the worst pictures Mr. Fenton exhibits, both as regards point of view, which produces an offensive series of parallel lines, one above another, without much apparent recession, and for the faults of treatment we have described

Closely allied in many of the characteristics to the photographs of Mr. Fenton this year are those of Mr. Lyndon Smith. Last year some of the photographs exhibited by this gentleman we regarded as amongst the finest shown, especially in the rare, soft, poetic rendering of atmospheric effects. We fear there is a slight tendency to carry this power to excess, and to let it become a mere *manner* which supersedes other beauties. We should regret this, as we regard Mr. Smith as one of our most artistic amateurs. No. 1, "A Glimpse of the Wye through the Yew Trees," may, on inspection possess many merits; but being as it is, high above the line, above the door in fact, and far from the light, it appears a sad unsatisfactory affair, and unworthy of Mr. Smith.

Bisson Freres contribute some good photographs of Alpine scenery, possessing great detail, vigour, and breadth. No. 35, "Vallée de Chamounix," and No. 47, "Savoie Pyramide de l' Imperatrice," are fine examples of their peculiar style.

Foremost amongst pictures possessing the second degree of merit, if not, indeed, quite amongst the first, are the photographs of Mr. Samuel Bourne. These are by the Fothergill process, and help to strengthen the position we have often stated, and pointed out last week as strikingly illustrated in this Exhibition—namely, that it is not in process that excellence depends. There is, as we stated, Mudd representing the collodio-albumen; Maxwell Lyte the metagelatine, Bedford, Heath, and a host of others, the wet collodion process, and here is Bourne representing the Fothergill process, all achieving the highest excellence.

Mr. J. Dixon Piper puts in a most excellent appearance at this Exhibition. His picture No. 121, "Lock Gates near Ipswich," is very fine both as a picture and a photograph. A "Study of Foliage," No. 155, is well chosen and beautifully rendered. An invaluable study for a painter. The same remarks are true of No. 251, "A Lane Scene."

Mr. F. C. Earl's "Panorama of Raglan Castle," No, 279, is a picture which has received, and is worthy of, much admiration. A large picture very perfectly photographed, and possessing many beauties, it is nevertheless somewhat marred in our eyes by the point of view, which presents an angle of the tower as a straight line right down the middle of picture, almost cutting it in two. The actual joinings—the picture being in three pieces—are most skillfully and judiciously managed.

Two "Views in Warwickshire," Nos. 175 and 176, by Mr. Josiah Spode, are well worth notice, they are brilliant and vigorous, but free from hardness. Major Gordon sends some excellent photographs from the Isle of Wight, warm in tone and perfect in manipulation, but unfortunately possessing white skies. Mr. Cruttenden's contributions to the Exhibition are amongst the best, and full of interest, we may especially call attention to No. 273, "Kit Cotty Stones," near Maidstone, Mr. T. Gillis's Vallée d' Argelez, with St. Savin in the foreground, is a very fine picture. "Fur and Feather," No. 437, an exquisite study of still life, exhibited by Mr. A. H. Talmadge, will receive much admiration. Mr. J. H. Morgan contributes a number of very excellent photographs, which we shall notice more in detail in another article, as also the fine pictures by the waxed paper, and collodion processes, by the Rev. T. M. Raven. "A Frame of Studies," No. 534, by Mrs. Verschoyle, are worthy of attention, not simply because they are the productions of a lady amateur, but for their own intrinsic excellence.

ERRATA.—In our last week's notice of the Exhibition a somewhat curious literal error occurred. In speaking of Mr. Fenton's pictures we wrote, "there is, perhaps, in some of these a slight tendency to a uniform lowness of tone and want of vigour." The printers substitued for "lowness of tone," "looseness of tone." A facetious friend has remarked that he thought it was a new-coined phrase in critical terminology, intended to indicate the opposite of "fastness of colour," and meant that the tones were not permanent.

We may also here state that we are informed by Mr. Robinson that the price quoted in the catalogue for his "Holiday in the Wood" is an error: 22s. is a misprint for £2 2s. It is amazingly cheap at that sum.

Scientific Gossip.

THE results of some very interesting researches have recently been communicated to the scientific world by Professor Bond, having for their object the examination of the light of the moon and the planet Jupiter, and embodying the results of photographic and optical experiments on the light which these heavenly bodies transmit to the earth. These two bodies, being each illuminated by the sun, might be supposed, at first thought, to reflect the visible and chemical rays to the earth in just the same ratio. This is, however, found not to be the case, the rays from Jupiter having been discovered to possess a remarkable degree of chemical energy, compared with those reflected from an ordinary opaque substance on the earth, and from the moon; similar excess exists in the optical brightness of this planet. The chemical *albedo* of Jupiter, supposing the planet to reflect light after the usual manner of opaque substances, exceeds that of the moon in the proportion of fourteen to one; the optical in the proportion of eleven or twelve to one. These experiments are open to the large uncertanties to which photometric comparisons are ordinarly liable; but assuming their correctness, and that as there is good reason to suppose the proportion of sunlight evident on the moon which is absorbed at its surface, compared with the amount reflected, is less than the smallest of the above-named ratios, it would follow that the planet shines in part by native light, agreeably to the old notion of phosphorescence. It is difficult to put any other construction upon the experiments, provided that Lambert's theory of the quantity of sunlight reflected to the earth from a planet is applicable in the case of Jupiter. Perhaps a more acceptable explanation is to suppose that its surface has the property of returning towards the sun a disproportionate amount of the whole quantity reflected, taking ordinary opaque substances as a standard. That this condition obtains with the moon may be inferred from the fact that at the full, the margin of its disc is brighter than the central regions, indicating a peculiarity in the constitution of its surface, which would be likely to produce an excess of brightness at full moon. It is, moreover, placed beyond question, from a consideration of the observed variations of the illuminating power of the different phases of the moon (of which a detailed account is given in the complete memoir of Professor Bond), showing that the theoretical representations of the intensity of moonlight in its changes from new to full, and *vice versâ*, as investigated by Euler and Lambert, bear no resemblance to the actual variations in the amounts transmitted to us. As Jupiter always presents a nearly full phase to the earth, a similar property of reflection in its surface would tend to explain the anomaly. There is, however, this objection to that hypothesis: while the superior marginal brightness of the full moon, whatever may be its cause, would naturally lead us to anticipate just that deviation from Lambert's theory of the amount of illumination derived from it which is actually observed to occur; the reverse order in the distribution of light over the disc of Jupiter, namely, its regular increase from the margin to the centre, in very good accordance with the same theory, is a strong argument for considering the latter as properly applicable to the planet; in which case the explanation suggested would no longer be admissible.

Photographers spend so much of their time in rooms which have to be illuminated by artificial light, that they will feel especially interested to learn that by some recent improvements there is a strong probability of relief from those impurities which render illumination by gas so prejudicial except in well ventilated apartments. A paper by the Rev. W. R. Bowditch, read before the Royal Society, describes a series of experiments upon which he has been engaged for the purpose of removing sulphuretted compounds from coal gas. Hitherto the bisulphide of carbon has resisted all attempts to remove it, and scientific men have been forced to confess themselves baffled in their experiments, but Mr. Bowditch has now found that by passing gas containing this deleterious ingredient over dry slacked lime heated to a moderate temperature, the sulphur is evolved in the form of sulphuretted hydrogen, having left the carbon, and being now in a state easily removable by many well-known and commonly practised methods of purification. In a former "gossip" we gave an account of some researches of Hoffmann, in which he had discovered a very delicate test for bisulphide of carbon, and we there stated how injurious this body was in illuminating gas; we are glad to be able now to state that, as soon as the above-named purifying process shall be generally adopted by the large gas companies, most of the serious objections which have been entertained to the introduction of gas in exhibitions, picture galleries, libraries, and private houses will be removed.

At the last meeting of the Manchester Literary and Philosophical Society, an interesting observation of Professor Arnaudon, of Turin, was mentioned, to the effect that oxalate of ammonia completely modifies the action of yellow prussiate of potash, when used in solution with a salt of peroxide of iron. Thus if oxalate of ammonia be added to this metallic salt, it will give no prussian blue when a solution of yellow prussiate of potash is added; but on the addition of an acid, prussian blue is immediately produced. The knowledge of this fact will be of interest to photographers, as these agents, both singly and combined, have been frequently proposed to be employed in various printing processes.

At the time of the occurrence of the eclipse of the sun in July last, we mentioned a series of photographs which had been taken of the progress of that phenomenon by

Messrs. Spiller and Crookes. We had recently an opportunity of seeing the complete series, which, appropriately mounted, formed one of the most attractive features in the library of the Royal Institution, on the occasion of the opening meeting of the season on Friday last. The complete series of photographs was mounted in one line, and was so arranged with the description, that it conveyed to the eye of the observer a complete panoramic representation of the passage of the moon across the solar disc. The frame likewise contained a series of photographs of the 1858 annular eclipse, and some of the unobscured solar disc, showing a gigantic spot in a very striking manner.

Another patent involving the employment of a bichromate! Mr. G. Wallis patents new or improved methods of preparing photographs, &c., for the purpose of engraving the same on metal plates, and thereby producing printing, embossing, or ornamental metallic surfaces. The patentee claims first the method, or methods described of preparing photographs, for the purpose of impressing or engraving the same, in or upon metallic surfaces, to produce printing, or embossing surfaces, by the use of mixtures, or compositions, consisting essentially of purely pulverised hard granular substances, and softer bodies of mineral, or vegetable origin, mixed with some glutinous body, such as gum aribic; which mixtures constitute drawing materials, which will flow easily from a pen or brush, and which, when dry, will form a substance sufficiently hard to impress metallic plates when subjected to strong pressure thereon. Secondly, the use of bichromate of ammonia, or other soluble chromic salt, as a fixing constituent in mixtures, or compositions, to be used for preparing photographic pictures, to be afterwards impressed, or engraved upon metal surfaces as described. Thirdly, the production of a tint upon a metal surface, when impressed with paper or other material, upon which the photograph has been made, and the treatment therewith with scraper and burnisher in the manner of a mezzo-tint engraving, for the production of effects of light and shade, when printed from in the manner of a copper-plate. Fourthly, the method of redamping photographs which have been previously treated, as before described, for the purpose of supplementing the same with granular powders. Fifthly, the general arrangements or combination of parts of the machinery described.

The above brief abstract will serve to give our readers a sufficient idea of what the inventor proposes to effect. We confess we have little expectation of the patent ever becoming of much practical value.

THE LIME LIGHT.

ITS APPLICATION TO PHOTOGRAPHY.

ANY experiments with the lime light for photographic purposes must have interest with the readers of the PHOTOGRAPHIC NEWS, I now propose, therefore, to lay before them a few hints derived from my own practice in this direction.

The lamp and apparatus I have used is one which is patented by Mr. Prosser, and is of a similar character to that employed by Dr. Pepper at the Crystal Palace. The lime is enclosed in a metal case, which is kept moving within a second metal case either by clockwork or other means, thus maintaining an equal focus and amount of light thoughout the experiment.

It is found that although the light is produced with great effect when carburetted hydrogen or the common coal gas of the streets is used in combination with the oxygen, still this illuminating power does not contain the necessary freedom from colour, that is at all times essential to a good photographic result.

The light so produced is nevertheless capable of being used for photographic purposes, provided its rays are concentrated by means of a powerful lens. The one I have used in some of my experiments is what is called a "lamp lens," being in fact the ordinary plano-convex or condensing lens of the magic lantern. This kind of lens has however the disadvantage of destroying in a great measure the chemical or actinic property of the light either by absorption or otherwise.

It is much better to use one made of pressed glass, called a parabolic lens, and known as Degrand's patent pressed lens; the quantity of glass through which the rays of light have to pass is thus reduced from about 6 inches to half an inch, the value of which reduction is obviously considerable.

But to return to the lime light, I may state when using the coal gas as one of the combined gases and not using a lens, I have invariably perceived the existence of colour to a slight extent, but this is less apparent when the rays are concentrated by the lens. In the first instance five minutes will not produce a picture, in the second instance five seconds will produce one; but in the latter case I have had everything in the same condition as if I were taking instantaneous pictures by daylight.

It is an easy matter to arrange the camera and lamp for portraiture, and to use lens, or reflector, or both; the latter method reduces the exposure, but it is considerably more objectionable to the sitter.

It is also an easy matter to copy by means of the camera, when the condensing lens is used with the lime light; I have taken pictures by this means with the same exposure I should have given to a picture in diffused daylight, viz., two minutes; but this must of course depend upon the distance the light is from the object, and the colour and nature of such object; the aperture of the jet; the pressure on the gas bags; the purity of the gases; and the colour of the paper on the walls of the room; the result is affected in a greater or less degree by all these matters.

Pure hydrogen and pure oxygen should be used in the proper proportions, this is instantly ascertained by the light given out; should either gas be in excess the effect is apparent to the operator. These quantities are regulated by the stopcocks for that purpose.

The light being free from all colour, the lens and reflector may for portraiture be dispensed with, but in copying by means of the camera they may still be used to save time. The copying lens will not be found to bear much stopping down unless the light is powerful and pure; a few trials will soon convince the operator of the right course to pursue.

Printing by superposition is also to be accomplished by means of the lime light; Mr. Malone, in a recent paper has stated that the electric light will print a picture in this way in fifteen minutes. It is a more intense and actinic light than the lime light, but at the same time it is thirty times its cost, and has neither the volume or the steadiness and continuity of the lime light. The power of the latter, unassisted by lens or reflector, for this kind of printing, and when at some little distance from the prints, is equal, if not superior, to that of diffused daylight; but when the picture is brought near to the light, or a condensed ray is thrown upon it, it has almost equal effect to moderately powerful sunshine. It is worthy of remark, however, that the rays of light emanating from the incandescent lime, and as I have previously stated, unassisted by lens or reflector, are not of that diffusive character as to give a weak picture, although the time may be prolonged in which it is obtained, the resulting proof will in the end equal that obtained in the strongest sunlight, provided the negative is not too opaque, or that the light is not too weak, from any of the causes I have enumerated.

As regards the adaptation of the lime light to the solar camera, it must be obvious that if a picture can be copied in five seconds the light having to pass through a condensing lens and afterwards through a portrait combination, it can be enlarged or copied upon an enlarged scale by means of the solar camera with these lenses. The only difference in the arrangement being, that in the solar camera the rays of light would pass (so to speak) direct upon the sensitive plate or paper, and in the ordinary copying camera the process would be effected by reflexion.

The advantage therefore must be with the solar camera.

By using the paper prepared as recommended by Mr. Sutton, for use with the solar camera,* and proceeding by development, the exposure would, with a powerful lime light and proper apparatus, be about six minutes.

All this may be done provided the essentials are correct and in order, but should one of them be wanting, no dependence can be placed upon the results, either as regards the length of exposure, or the quality of the picture.

The lime light is one of the most valuable friends a photographer can have, and nothing can be more simple than its management, provided ordinary care is bestowed upon it. S. S. B.

PREPARATION AND ANALYSIS OF THE IODIDES.

BY M. A. GAUDIN.

IODIDE of silver is the very soul of photography. Up to the present time, every process for obtaining images (negatives) has been based upon the employment of iodide of silver.

The first indication of the visible modification of the compounds of silver by light were made, it is true, before the iodide was discovered; chloride of silver, which is so often produced when operating with salts of silver, rapidly changes its pure white colour for a slaty hue under the influence of the diffused light of the laboratory. This chloride was regarded for a long time as the body most sensitive to light. After the discovery of bromine, a similar remark was made upon bromide of silver; while iodine, which had preceded bromine, did not appear to produce an iodide of silver so sensitive to light.

It was on this account, generally, that the attempts to produce images by light revolved continually around the employment of chloride or bromide of silver. Five or six years prior to the publication of the discoveries of Niepce and Daguerre, I was engaged in obtaining images by light, and I did not omit to make use of chloride of silver precipitated on paper; but my operations were limited to the production of silhouettes of the wings of insects by means of the direct light of the sun, and I could only preserve the pictures by sheltering them under red glass.

Upon the announcement of the photographic discoveries of Niepce and Daguerre, but before the publication of their processes, knowing only that they operated upon silver, I also made use of chlorine, but without any apparent success.

Niepce, who produced his pictures by means of bitumen, modified by light, at first employed iodide only to blacken the silver, in order to bring out his heliographs, which were visible only by reflection, as in Daguerre's process; and doubtless a plate left to itself with any object placed on its surface, will show the imprint of that object, after a prolonged action of diffused light; for, as all who have practised the Daguerreotype process well know, an iodized plate, which, in the first moments of luminous action, does not at first appear to change its colour, subsequently assumes every imaginable hue.

Whatever it be, the Daguerreotype process is based essentially upon the employment of iodide of silver, notwithstanding the increased sensibility it receives from the addition of bromine and chlorine. The collodion, albumen, and paper processes have also iodide of silver for their principal basis.

I am astonished to find that many persons maintain that this is due to a mathematical cause. I have on a former occasion shown, when speaking of certain properties of light, that the distinction of colours, which is generally perfectly defined, depend, nevertheless, upon the comparison of two sensations, differing from each other in time and length, by a quantity unimaginable by its minuteness.

In the present case the cause is evident, the fact is before our eyes. If, for instance, we enquire which of the simple metallic bodies possesses the greatest atomic weight, we find that it is silver; if we next enquire which mineralizer possesses the greatest equivalent, we find that it is iodine; if, lastly, we enquire what binary compound of the simplest composition which possesses the greatest atomic weight, we shall have for a reply—iodide of silver.

The atom of silver weighs	... ...	108
The equivolent of iodine	... ...	127
Hence the equivalent of iodide of silver is		235

The other precious metals, the oxides of which are easily reducible, such as gold, platinum, iridium, asmium, mercury, lead, and especially bismuth, have a very high atomic weight, while the difficultly reducible metals, such as calcium, magnesium, sodium, &c., have a very low atomic weight. These examples suffice to prove the reality of this cause, for notwithstanding apparent exceptions, a profound examination will show that in general affinities are much more energetic, and consequently, the resistance to decomposition by light is much greater when the atomic weight of the combined bodies is the least; and for the same reason, also with light atoms, the alteration by light is also manifested upon the very heavy molecules, on account of the greater number of atoms of which they are composed. The composition of iodide of silver is of the simplest, but the atoms of which it is composed are very heavy; so that in order to arrive at as great a sensibility with compounds, formed of light atoms, would require a very complex formula, such as is presented generally by resins and analagous bodies.

The first employment of iodide of silver in photography occurred in a very simple manner, in Daguerre's process it is polished silver which is submitted to the vapour of iodine. The silver itself, by a process previously brought to perfection, was fixed upon the copper, in layers as pure and homogenous as could be desired; it is a metal which very readily receives a polish, and iodine is the most suitable substance to produce a vapour which shall increase with the temperature; so that the sensitive layer of iodide of silver is readily produced by exposing the polished silver plate in a box containing a few grains of iodine covered with cotton.

The combination is easily effected by this arrangement; the silver becomes covered with a golden yellow film, composed simply of iodide of silver, of an extreme tenuity, almost refusing to be analysed, and organised in a manner that science cannot define: on account of the phenomena of cementation, necessarily produced, the silver and the iodine, being each in excess, the iodide of silver is poorer in iodine where in contact with the silver; this constitution, which produces a certain molecular tension, also facilitates its decomposition by light, the principal effect of which is to invest the composition of the iodide of silver. After the action of the light the iodide of silver is poorer in iodine on its external surface, which previously was the richest in iodine.

(To be continued.)

PHOTOGRAPHY AS A FINE ART.

THOSE who deny to Photography the right to be ranked among the Fine Arts may be surprised to learn that it requires a greater variety of talent, and that of a high order, to produce a good photographic picture, than it does to cover a square yard of canvass with a picture eligible as an Art-Union prize. The manipulations of the painter are few and comparatively easy of acquirement. Crayons, pencils, and pigments, handled with perseverance and taste, soon enable the painter to produce a result which shall astonish the vulgar. But the photographer, to succeed in his vocation, must make himself familiar with chemical phenomena and optical laws, and superadd to these (usually regarded as the only needful guides), a knowledge of those principles of art which the painter arrogates solely to himself. The photographer must not only study and master the principles of chiaroscuro, but he

* We will give the formula in an early number

must also be able to control the chemical agencies by which he obtains his results, so as to ensure the end proposed. The difficulties that beset the photographer in this direction are almost incredible; and so far from this new art being regarded as a mechanical one because the picture is drawn by Nature's own finger, acting through a mechanical agent. the result will depend, for its artistic excellence, entirely on the knowledge and taste of him who directs the lens to the object represented. This fact is strikingly shown in pictures of the same inanimate object taken by different photographers: it is easy to pronounce, at first sight, whether a view of Ben Lomond has been taken by Fenton or Heath, by Bedford or Llewellyn; for, like the painter, the photographer has his *manner*, and this manner is the exponent of his judgment, taste, and feeling. His judgment is shown in the selection of that hour of the day at which the object exhibits the best play of light and shade, the most perfect chiaroscuro; his taste will display itself in the selection of the best point of view, so that all harshness of outline be avoided, and unfavourable accessories omitted; his feeling will will be exhibited in the choice of the subject itself. One revels in moss-clad ruins; another in bosky dells; others in the misty morning landscape, or the wave-beaten sea-shore.

But it is in portraiture that the supreme difficulties and triumphs of the photographer are encountered. In this sphere of his art we look in vain for the Titians, the Rembrandts, the Vandycks, or the Gainsboroughs. Occasionally we meet with photographic portraits that remind us of these masters of the "human face divine;" but it would seem, from their rarity, that they must be the result of accident rather than of design. And this deficiency is no reproach even to the artist-photographer; for he may prepare his chemicals with the most scrupulous care, plant his camera on the chosen spot, pose his model with consummate skill and taste so as to obtain a Rembrandtist effect of chiaroscuro, yet the resulting picture may both astonish and disgust him. All his skill, care. and taste are baffled by a subtle and unfamiliar agent—the chemical action of light—which refuses to do his bidding, which will translate his conception neither literally nor poetically, but after a fashion and a method of its own. This obstacle to successful results is greater than any the painter encounters, except lack of genius, and it requires more patience and skill to overcome, than to master all the arcana of "high art." The photographer, like the engraver, produces his effects by light and shade; he owes nothing to colour; and being deprived of this latter attractive element—which covers so many defects in painting—his chiaroscuro need be the more perfect. It is but too evident, from the abundance of bad photographic portaits, and the extreme rarity of those that are truly excellent, that this great obstacle to success is seldom overcome; nor, seeing the rare combination of talent that must unite to form the perfect photographer, can we hope to see it overcome to any extent. Many eminent continental artists have become photographers; early familiarity with chemistry has enabled them quickly to overcome the mechanical element of the art; their art-culture has supplied the rest. Productions of artists of this class are prized as highly, in comparison, as the choicest easel productions of contemporary portrait-painters; and deservedly so, inasmuch as they contain an element of truth beyond the reach of the pencil, by whomsoever handled.

The sphere and power of photography have been greatly misunderstood. Like every art it has its boundaries, within whose limits it may become unrivalled, without encroaching upon the domain of other arts. It cannot rival painting as it is deficient in the attractions of colour. Yet this latter element is the one that can be easiest dispensed with in a work of art. In the presence of the cartoons of Kaulbach, or of the "Dying Gladiator," we are conscious of no loss of expression arising from the absence of colour. Rembrandt made no sacrifices to colour in his magical preductions, but impressed the mind of the beholder through the influence of his masterly chiaroscuro. In the truthful rendering of chiaroscuro lies the magic power of photography: it translates the marvellous play of Nature's light and colour into a sober page of black and white, which the eye can reclothe in its pristine hues. The absence of colour in photography is, in fact, no loss but a gain, for it leaves the eye undisturbed in its contemplation of form and chiaroscuro. It possesses the high merit of affording a means of educating the eye to a just appreciation of outline and form. And it came very opportunely to this end; for the public taste, vitiated by the gaudy productions of a large class of mediocre painters, who had run riot in colouring, needed some truthful guide to restore to it its pristine power of discrimination. The glowing prismatic hues of the puny imitators of Turner dazzled the eye and cheated the judgment of both critic and public, and had not the colour-fever been checked by the advent of photography, the time would not have been very far distant when the British artist would have become incapable of drawing a hand or a foot with tolerable accuracy.

The art that photography most resembles is engraving. In both the object is represented by form and chiaroscuro. But photography is limited in its range. It can only represent actualities, it cannot create subjects. As the hand of man can neither change nor modify the photographic image, the art sinks below other arts which can embody man's creative power. The sculptor can create his Appollo or Hercules—photography cannot create such subjects, but only represent those that are created by the effort of man's genius. While photography is superior to engraving in its power of faithful delineation. it is inferior to it from the absence of creative power, for the engraver is not limited to the delineation of existing objects, but uses his burin as a crayon, and with it exercises his creative faculty.

But inasmuch as photographic results are governed or modified by the artistic culture of those by whom they are produced, we must admit photography into the category of fine arts. When its processes become more manageable, as much so, in fact, as the crayon in the hands of the painter, then will photography approach still nearer to a high place among the fine arts; for, inasmuch as being less dependent on manipulation, there will be the more room for the exercise and display of the artistic faculty. Every year brings us nearer to this desired consummation.

We watch, year by year, the development of the artistic element in photography in the Society's exhibitions. This year there are evident signs of progress. There are few very bad pictures, while the average is far above mediocrity. In landscapes, the productions of Fenton, Bedford, Heath, Mudd, Piper, Raven, Lyte, and some others, are noteworthy for a genuine appreciation of the artistic capabilities of their subjects. In portraiture the coloured specimens are greatly in the majority, and the pictures of Carrick, Claudet, Lock, Whitfield, Gust, and Ferguson arrest the attention of admiring crowds. Two large views in Rome—the Colosseum and the Church of St. Peter—the work of P. Dovizielli, are marvels of art. There is the usual quantum of contributions from amateurs, neither remarkable for excellence, nor particularly interesting for their subjects. We miss many names of those who have powerfully contributed to render the art as excellent as it has now become. and we may justly deplore the extremely narrow limits within which this wonderful art continues to be exercised. There is abundant display of dilettantism, but little of genuine connoisseurship. With the boundless wealth in art possessed by this country we ought to have been made much more familiar by the aid of photography than we now are. Looking at the unlimited resources of photography, we must confess ourselves disappointed at the poverty of this year's exhibition.—*The London Review.*

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held on the evening of the 17th inst., the Rev. F. F. STATHAM, B.A., F.G.S., occupied the chair.

The minutes of the former meeting having been read and confirmed, the secretary read a letter from Mr. Bailey, of Darlington, one of the society's provincial members, describing the specimens from waxed-paper negatives he had forwarded to the society's portfolio, and presented at the last meeting. One was by the Rev. T. M. Raven, and the others by Mr. Hooper of Manchester. Another letter was read from Mr. Bolton, wood engraver, enclosing a copy of a communication to the PHOTOGRAPHIC NEWS, explaining that the engravings from Flaxman's bas-reliefs, appearing in the recently published *Lyra Germanica*, were photographed on wood and engraved by him. The secretary also announced the gift to the society's library by G. Wharton Simpson, of a copy of "The Photographic Teacher," "The Principles and Practice of Harmonious Colouring applied to Photographs," and "The Photographic News Almanac."

The following new members were proposed and elected during the evening—Messrs. Foxlee, J. Warner, J. H. Symons, Sydney Smyth, and James Contenci; the latter gentleman presented some specimens of a process of photo-lithography, on which he was engaged in experimenting, and which, though as yet imperfect, had many features of promise.

T. BURR, Esq., F.R.A.S., then proceeded to give an eloquent and highly interesting account of the history of photography in connection with the sciences of astronomy, meteorology, and magnetism. After explaining that his presence amongst them was due to the urgent invitation of his friend Mr. Wall, he proceeded to glance at the earliest applications of photography to astronomy. The first publicly exhibited specimen was a Daguerreotype of the full moon, which was taken at the observatory, at Cambridge, Massachusetts, U.S., and exhibited at the Great Exhibition of 1851. It was taken by a refracting telescope of fifteen inches aperture, perhaps the finest in the world, the gentlemen who produced the picture were Messrs. Boud, Whipple, and Black. In the year 1851 the collodion process was introduced by Mr. Archer, and in 1852 Mr. Warren de la Rue made some attempts to photograph the moon on collodion plates, and produced a positive an inch and a half in diameter, which was shown at the meeting of the Astronomical Society in 1853. At that period he had no driving machinery to enable the telescope to follow the moon's apparent motion, he was obliged to have recourse to the assistance of some one to assist him in making the telescope do this, and Mr. Thornthwaite afforded him valuable aid. The difficulties were, however, so great, that Mr. De la Rue gave up the experiments until he was able to apply driving machinery to the telescope. In the year 1853 Professor Phillips applied photography as a means of getting pictures of the moon, using a telescope of six inches aperture. In 1854 some pictures were taken at Liverpool, by Mr. Hartnup, Mr. Crookes, and some other gentlemen, using a refracting telescope of eight inches aperture. Father Secchi, at Rome, with a telescope of nine inches aperture, produced pictures of the moon, and subsequently Mr. Fry, at Brighton, and Mr. Huggins at Tulse Hill, had commenced their operations. Mr. Burr then proceeded to explain the difficulties which beset the operator when using a refracting telescope, on account of the variation of the chemical and visual foci, the actinic focus generally falling beyond the visual to various extents, in the telescope of Mr. Huggins, to the extent of three-fourths of an inch. In the reflecting telescope this difficulty was obviated, and the operation of focussing was easy enough. In 1857 Professor Boud turned his attention to the collodion process, and sent over to this country some pictures of a fixed star and its companions. One great advantage of this achievement, was the fact that careful and actual measurement could be applied so as to ascertain their distances, positions, &c., with much more accuracy than could be done by the usual process with a micrometer. Professor Bond also sent over a picture of a fixed star passing over his transit telescope, exhibiting a distinct line of light passing across. It was blurred and irregular, owing to varying atmospheric conditions. In 1851 he obtained some Daguerreotypes of double stars. Mr. Burr then proceeded to a brief detail of the operations of Mr. Warren De la Rue, and his method of applying clockwork to cause the telescope to follow the orbital course of the heavenly bodies, and also his general method of working. In the course of these remarks he observed that Mr. De la Rue had not found that loss of actinic power from employing a second reflection that his knowledge of the loss of luminous power had made him anticipate. The negatives of the moon produced by different experimentalists varied in size, depending upon the powers of the telescope used. Some were as small as a fourpenny piece: others were as much as three inches in diameter; whatever the original size, they could of course be produced of any dimensions required by a subsequent process of enlargement. The phenomenon of libration, and the facilities it afforded of obtaining stereoscopic pictures of the moon, was next explained with much lucidity. Some interesting details regarding photographs of the stars followed, in the course of which it was stated that Jupiter was considerably more actinic than the moon, although much darker in appearance so far as colour was concerned, whilst Saturn was much feebler in actinic influence. Some details of Mr. De la Rue's experience in photographing the sun, and the use of the photo-heliograph were then given, and a few particulars of the only photograph of Donati's comet followed. This was taken by Mr. Underwood with a common portrait lens in seven seconds.

Mr. Burr then proceeded to give an interesting resumé of the various applications of photography to magnetic and meteorological registration. After pointing out the importance of a correct and reliable system of magnetic registration, and the impossibility of using mechanical appliances to perfect a system of self-registration, he proceeded to describe the beautiful contrivance which had been finally adopted to secure a photographic self-registration of every vibration of the magnet. It is somewhat difficult to do justice to the description without the diagrams; but we may briefly state the principle upon which the apparatus works. Attached to the suspended magnetic bar, the oscillations and declinations of which are to be registered, is a small mirror which reflects the flame from a lamp of napthalised gas, placed at a suitable angle. Every reflection or vibration of the magnet causes, of course, a similar vibration of the mirror attached to it, and every vibration of the mirror alters the angle of reflection of the light from the lamp. It will be readily seen that the vibrating ray of light reflected, if thrown on a screen, would describe a series of zigzag lines, the indentations being in proportion to the distance of the screen, or the length of lever which the ray of light formed. Instead of a screen, however, this reflected ray is received on a sheet of sensitive paper, rolled round a glass cylinder, and which, to bring a fresh surface constantly under the point of this pencil of light, is made to revolve at a uniform rate by means of its connection with a chronometer. Every twenty-four hours the sensitive sheet on which this ray of light has traced the magnet's deflections is taken out and developed. From it a negative is copied, and then the number can, of course, be multiplied at will. Mr. Burr's lucid explanations, which we have barely indicated, were illustrated by diagrams, models, and specimens of various kinds, which materially added to their general interest. Fuller details on the absorbing subject of which they treat maybe found in the various papers on celestial photography, by Mr. Warren De la Rue, in our last volume, and in Mr. Glaisher's papers on "The Application of Photography to Investigations in Terrestial Magnetism and Meteorology," at pp. 45 and 138 of the second volume of PHOTOGRAPHIC NEWS.

The CHAIRMAN, in proposing a vote of thanks to Mr. Burr, expressed his regret that his address had not been in a written form, so that they might have hoped to have seen it again in its entirety. Photography seemed to have grasped the whole subject, and solved almost every conceivable problem, astronomical and meteorological. He thought there ought to be a special grant from Government to support a photographic staff at the Royal Observatory, so that such observations and records should not be left simply to the British Association.

Mr. JABEZ HUGHES thought if any one thing was more than another calculated to elevate the mind and make them enamoured of the lofty capabilities of their art, it was the influence of such eloquent and well-timed observations as they had heard from Mr. Burr. With what a strange and deeply reverential feeling must they all gaze on those mystic marks on the sheets of paper which had been passed round, and which were the self registered tracings of the magnetic deviations. They were in the habit of speaking in vague and general terms of a "pencil of light," of "the pencil of Nature:" here they had its actual embodiment, Nature recording her own operations, tracing her own eternal laws with her own pencil. There was also something strangely interesting in learning the fact, that actinism accompanied light in almost all its forms, and that the light from far distant heavenly bodies formed no exception to that law. That in some respects the laws of the universe, as relating to far off systems, were the same as that of the solar system, we had reason to believe; we knew they were subject to the same laws of gravitation. We saw they had similar light as regards illumination; but it was not until photography had revealed it that we knew that their light was essentially the same as ours, and that the light from the distant stars possessed actinic properties in common with our own. Referring to the first exhibited pictures of the moon, Mr. Hughes observed that there was something interesting in the fact, that the Daguerreotype process, just about to expire, seemed determined before doing so, to inaugurate the era of celestial photography, and contribute its especial offering in that form to that wonderful monument of the world's civilization—the Great Exhibition of 1851. The moon had been photographed, indeed, before that. In 1847, Mr. Mayall and himself took some Daguerreotypes of it. It was true they were small, and blurred from motion; but they served to prove the moon's actinism. There was just one remark made by Mr. Burr which demanded some attention, that was as to Mr. Warren De la Rue's experience on the subject of reflection, and his supposition that there was little or no loss of actinic power in a second reflection. That point required further examination Daguerreotypists who had frequently to use a reflector for the purpose of avoiding inversion of position in the sitter, knew well that they had considerable loss of light in using it, and a loss of actinism in just equal ratio. The time required was generally at least one-half longer; if 60 seconds were required by direct light, 90 were required when the reflector was used; and in dull light the ratio was still greater. There was another point to which he would just for a moment refer. It was stated that in the refracting telescope the visual and actinic foci did not coincide, and that this fact caused great difficulty in focussing, because the ratio of variation was constantly changing. Now this latter conclusion he could not admit. The early experimentalists in photography worked entirely with such instruments, and they obtained as good and sharp images as were obtained now. It was only necessary once to ascertain the amount of variation between the luminous and chemical foci, and make the necessary adjustment of the ground-glass and slides of the camera, and there was then no further trouble. M. Claudet had, it was true, at one time propounded a theory asserting this perpetual variation in the relation of the foci; but he did not remember that it had been practically confirmed by any observer. Mr. Fry had stated that in his lunar experiments he had suffered from a similar difficulty; he could not but think, however,—

Mr. Fry explained that Mr. Warren De la Rue had, at the parent society, a few evenings ago, satisfactorily explained his difficulty by suggesting that it was caused by the expansion and contraction of the tube from variation of temperature.

Mr. Hughes could hardly recognise that as meeting the case. Such contraction and expansion might alter the focus, but it would alter the visual as well as the actinic focus; it could not alter the relation of each to the other.

Mr. Burr suggested the varying refracting influence of upwards of forty miles of atmosphere.

Mr. Hughes still must maintain that all the circumstances that would affect the chemical focus, would, so far as optical laws were known, affect in similar ratio the visual focus.

A conversational discussion then arose on this subject, in which Messrs. Burr, Hughes, Fry, and Davis took part. The real source of doubt seemed to arise out of the fact that the various experimentalists had taken note of the varying actinic focus, but had not thought of observing, if, at the same time, the visual focus had altered; its stability having been merely taken for granted from the knowledge that it had been adjusted once correctly, and then not altered by any further adjustment or movement in the instrument.

After a vote of thanks to Mr. Burr, the discussion on the subject was adjourned.

Mr. Fry wished to make a few remarks on the late discussion on composition printing. His object was simply to claim for the photographer the same privileges and licence usually accorded to painters, which would permit them to print-in to their pictures such skies as the laws of composition and good taste should suggest.

Mr. Hughes briefly responded, to the effect that the object desired by both Mr. Fry and himself was the utmost possible excellence in the productions of their common art. They looked at the subject, however, from somewhat different points of view; his own conviction still being that the sole strength of photography lay in its inexorable truth.

The Secretary announced that at the next meeting a paper would be read by their treasurer, Mr. Frank Howard, on "The Successful Practice of the Fothergill Process."

The proceedings then terminated.

Manchester Photographic Society.

The usual meeting was held on the evening of the 9th, Edward Mann, Esq., in the chair.

The chief feature of the evening was the exhibition of some pictures by means of the oxycalcium light, superintended by Mr. Dancer.

Mr. Pyne exhibited some negatives taken by Mr. Sutton, of Jersey, on Dr. Hill Norris's sensitive plates, with an exposure similar to that required in the wet process.

After some announcements, and the usual vote of thanks, the meeting separated.

Birmingham Photographic Society.

The monthly meeting of this society was held on the 18th ult., C. L. Haines, Esq., presiding.

After some routine business, Mr. Rejlander read a paper, or rather delivered orally, on the camera of horrors, or difficulties and failures in the wet process, in which he stated his experience on the various subjects which try the patience and test the skill of the photographer; the bath and the collodion, the glasses and the dust, and above all the varnish, &c. &c.

After some observations by Mr. Osborn,

Dr. Anthony, in expressing his pleasure in listening to Mr. Rejlander, observed that he could not forget the fact that he had done more than any other man in England in rescuing photography from the purely commercial position it had a tendency to assume, and placing it in its rank amongst the arts. Dr. Anthony then made some interesting remarks on his own experiences and operating difficulties whilst in Syria. Regarding the cracking of varnished films, he believed it was generally due to the influence of damp, either in the film at the time of varnishing, or in the atmosphere where the negatives were subsequently kept

After the usual vote of thanks the proceedings terminated.

Photographic Society of Scotland.

The usual meeting was held on the 8th inst., A. G. Herries, jun., Esq., presiding.

After the usual routine process a silver modal was presented to Mr. C. G. H. Kinnear, for his valuable services whilst acting as secretary to the society, and for his invention of the portable camera now well known. After suitable acknowledgments from Mr. Kinnear, a communication was read by Mr. T. B. Johnstone on the malt process, in which he stated that almost everything depended on the preparation of the malt solution. The proportions he preferred were three of malt to twenty of water, which should be heated to about 175° before adding the malt.

Mr. J. T. Taylor read a paper on silver and some of its salts, illustrating the paper with few experiments. No discussion arose.

A letter was read from the Hon. H. Fox Talbot, expressing his regret that he was not able to be present at the meeting. He forwarded a large number of specimens of engravings by the photoglyphic process, which were much admired.

After votes of thanks the meeting separated.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 23rd January, 1861.

An article on "Photography as a Fine Art" in the last number of the *London Review*,* which I have just perused, together with the frequent discourses and discussions on this

* See p. 41.

subject, with which your journal abound, naturally suggest to an observer on this side the channel, the enquiry: how is it that this subject is in so quiescent a state here, and in so active a state of fermentation with you? Not that our quiescence is apathy, but it appears to me that from the first photography being with us in the hands of accomplished artists, it never had to go a begging to be admitted into the category of the fine arts. There is no subject on earth upon which more incoherent nonsense has been written and spoken than upon this subject, art. Yet art has its principles as well as science, which cannot be gainsaid, but for which dreamy wordy dogmatism is usually substituted, to the great bewilderment of the uninitiated, and the intense disgust of the earnest art-student. It is not necessary to enquire whether photography be an art or a manufacture, that will obviously depend upon the culture of the operator; the picture may be the product of the studio, it may also be the product of the workshop. If, as I divine, it has not, if photography has not yet assumed the rank of a fine art with you, it is doubtless due to so few photographers possessing artistic culture. Artists are not made in a day, though operators may; on the contrary, as the poet says,—'Art is long,' long in being acquired, because its sphere is so vast and complicated, that even Titian and Michael Angelo, to the last days of their long existences, thought themselves but apprentices. But sufficient of the principles of art—the laws of light and shade, chiaroscuro, and of colouring—may easily be acquired, which would suffice to guard the operator from the glaring violations of taste so frequently encountered. I am inclined to think that continental photographers enter upon their career with some advantages over those of England, inasmuch as the principles of science form an important feature in their elementary education, while familiarity with the canons of art, exemplified in what we call good taste, is more generally infused into every grade of society. I presume that if Photography were to knock at the door of your Royal Academy, the burly janitor would say, "No admittance," and slam the door in its face. But let not the artist photographer despair; for even the noble art of Engraving was not admitted into that close corporation until nearly a century after it had been established. Here, favoured Photographers rank with Academicians; they are among those whom the Emperor delighteth to honour: for he, with no niggard hand, awards them crosses, and decorates their breasts with a much-coveted bit of ribbon, proclaiming the wearer member of the honoured Legion of Honour. Happy land! happy photographers! They wear no honours but those they have justly earned.

Mr. Roth of Mulhouse, has perfected a process of purification of colza-oil, so as to render it unoxdizable, and suitable for lubricating machinery. This process is by the dry way, the most energetic, rapid, and economical. By heating the oil to a very high temperature, the water and volatile products are driven off; the foreign albuminous and pectinous matters, &c., are dehydrated, coagulated, and speedily undergo decomposition, manifested by the pungent vapours given off. The oil must be heated sufficiently for this alteration to take place, but care must be taken not to raise the temperature so high as to decompose the oil itself, when glycerine or acreoline, the result of its decomposition, are disengaged, and the free fat acid becomes dissolved in the oil.

The limits of temperature would be very difficult to follow in practice, and probably the elimination of foreign matters by this kind of torrefaction alone would be insufficient, if the idea had not occurred to Mr. Roth to introduce a compound capable of hastening the alteration of the impurities, and at the same time facilitate the reparation, by forming with them compounds insoluble in the oil.

This part is performed by a minium or peroxide of lead, abandoning at this elevated temperature of the oil a small portion of its oxygen, it oxidizes without entirely burning the albuminous matters, while at the same moment plombic oxide is generated, which is a very powerful base, with a strong tendency to combine with the abluminous, saccharine, pectinous, and other matters, is there to carry off the oxidized matters.

The colza-oil itself undergoes no change, and when its impurities have subsided, pyroleine of the colza represents the trassine and oleine of this oil in a state of great purity, without the quality or physical properties of the oil having undergone notable alteration. It contains only the slightest appreciable traces of lead, not amounting to $\frac{1}{1000}$th part. Careful experiments, instituted for the purpose, show that this oil thus treated, is in every respect equal to sperm oil, as a lubricator; and that machinery oiled with it continued working twelve successive hours without the bearings becoming heated. This result is of eminent importance to the manufacturing interest, seeing that colza-oil is not half the price of sperm oil.

M. Emile Rossaau has made a very important communication to the *Academie des Sciences*, on an improved method of purifying vegetable juices employed in the fabrication of sugar. Two kinds of organic substances obstruct the extraction of the sugar from these juices; the first kind belongs to the group of albuminous and caseous bodies; the second is a colourless substance, very greedy of oxygen, which quickly becomes coloured under the influence of the atmosphere, and is rapidly modified by the agents of oxidation. It becomes necessary to find, 1st, a substance generally but little soluble, which can coagulate all the albuminous matters, which can be easily removed from the juice in the event of any remaining in solution, and lastly, of a low price; 2nd, of another substance possessing a limited oxidizing power, which by its action can destroy the colouring matter, or transform it into a brown matter, and afterwards absorb it, and lastly, combine with the qualities of innocuity of action of the preceding body, a very low price. The body which appears best adapted to meet the conditions required is sulphate of lime, either natural or artificial. It is neutral, but slightly soluble, and without any action upon the sugar, and it is of very low price; to the condition of innocuity it adds a very remarkable power of coagulating the albuminous bodies in vegetable juices. This property is so striking, that a very small quantity is sufficient to produce the desired effect. It completely removes all coagulable matters, forms a very thick scum, and leaves the juice in a perfect state of limpidity, but it does not touch the colouring matter.

Animal charcoal is almost without effect on the colour immediately after the purification of the juice, it only removes the oxidized matters; for after it has acted upon the juice and deprived it of its colour, the juice soon becomes coloured again. An oxidising body, therefore, is required which can accomplish in a short time what the atmosphere requires a long time to effect, and which can so modify this colouring material as to absorb or destroy it. Among the substances experimented upon, the hydrated peroxide of iron presents the greatest advantages.

Thus, after all, the coagulable matters are removed from the juice by the sulphate of lime, it is agitated with a quantity of hydrated peroxide of iron, the liquor passes through the filter colourless, and purified from all foreign matters of every kind it may happen to contain. By the property peroxide of iron possesses of absorbing earthy and alkaline salts, the sulphate of lime which remained in solution, is removed from the juice, which readily crystallizes, free from any acrid or bitter taste, and it is, moreover, perfectly neutral to test-paper. The price of peroxide of iron is much lower than that of animal charcoal. The complex process of purifying saccharine juices is now reduced to one of extreme simplicity, which leaves nothing to be desired.

M. Girardin, in examining the solvent properties of bichloride of tin, or liquor of Libavius, finds that it is almost equal in that respect to sulphide of carbon.

M. Sudre, by an experiment which leaves no room for doubt, has confirmed the curious and important fact established by M. Boutigny—that the temperature of water, or of the globule of water in a spheroidal state, is 205° or 206° F., less than that of boiling water. The certain mode of verification adopted by M. Sudre consists simply in introducing the globule of water, into a calorimeter, and directly determining its temperature by the quantity of ice it causes to melt.

LONDON PHOTOGRAPHIC SOCIETY.

SIR,—I feel reluctance in again addressing you; but "A Former Member" has, while professing sympathy with me, expressed his views in such a manner and spirit, that in self-justice I feel bound to exclaim, "Save me from my friends." However he may agree with me, I strongly dissent from him; for no reform can ever be aided by rudeness of language or coarseness of manner. My only aim was and is, to call attention to present shortcomings, and to stimulate those who have our society's management to more vigorous action; as well as to express my doubts of the wisdom of the course of electing certain gentlemen on the council, of whom we have not had sufficient evidence of their fitness.

The next meeting is the annual one, and the only one throughout the year, when business matters may be discussed; and it will be seen if it pass over without some effort to amend matters.

In my former note, I attributed most of the deficiencies to the constitution of the society, and I still think so. I think it wrong to have so many gentlemen on the council; the responsibility is too divided and diffused. Half the number would manage it better, and have more credit and pleasure in doing it. The council should mix more with the members, letting them see who they are, and what they propose, and thus obtain their sympathy and support. They should not be elected for three years, with one-third going out annually; they should all go out every year, subject to re-election. There would be no fear of their losing their seats; good men are always appreciated. When elected, they should divide themselves into committees, according to their special abilities: one undertaking the internal affairs and general business; the other, fully alive to the vital interests of the art and science, forming their plans for improvement, extension, and development.

Photography is confessedly immature, and requires culture, guidance, direction. Except the PRINTING-PRESS, there never was an ART took such firm and vast hold of humanity. What was a toy has become a necessity. It is spreading everywhere; high and low, rich and poor alike partake of its blessings. It is potent for good and ill. It can hardly go lower, but how much higher may it not ascend? And who shall take it in charge? Who shall assist its aspirations? Whose duty is it, if not ours; for, to whom has it been confided, if not to us? Who are the photographic Titans but Fox Talbot and Archer? and where have they lived, moved, and had their being, but among us?

Our society, therefore, ought to be the chief of societies—a very Royal Society—taking the lead of all others,encouraging and setting them a grand example—a home where the noblest of the land might come and sit—where the highest Art and deepest Science should teach—whose meetings should be anticipated with ardour, and remembered with delight.

I would have our society one to which it would be an honour to belong, and a privilege to address; and to which access should be sufficiently difficult that, when obtained, it should be highly prized.

I would have an honorary council, or board of patrons, and a practical energetic one for managing its affairs. The former should be composed of the highest and wisest in science and art, who might be consulted on occasions, but who would not be expected to attend to details of business; and the latter, of men deeply imbued with our art, and anxious to aid its onward course.

Such is a hasty sketch of what I think might, ought, could, and should be done to render our society worthy of its high prestige and the original impulse with which it was projected.
PROGRESS.

PAPER POSITIVES DIRECT IN THE CAMERA.

MR. EDITOR,—In conjunction with a photographer of Cornwall I tried some experiments, during the last summer, in taking paper positives direct in the camera. The process is so far successful that I should be glad if you would communicate the same to your readers, in the hope that some of them may be induced to make trial of the same, and make improvements on the process; with some modification of the chemicals employed, it is capable, I have no doubt, of excellent results. Out of several methods, the following is the most satisfactory:—

Print photographic paper to blackness, fix and wash in the ordinary mode of photographic printing; dry; cut the paper to the size required; gum the back with gum dissolved in distilled water. Attach the paper to the middle of a well cleaned glass plate, one photographic size larger than itself. Dry flat under a slight pressure. Pour on and off albumen previously shaken in a bottle, with a little distilled water and a drop of glacial acetic acid.

It will be none the worse to repeat this albumenizing two or three times as the paper dries. When dry, coat, taking care that the collodion flows beyond the edge of the black paper; allow it full time to set. Now sensitize and expose for about the same time as a glass positive; develop with iron, &c.; fix with hypo or very weak cyanide; wash well; leave the picture soaking for some time in changes of water. If spots appear on the picture, they will gradually disappear in the water bath. Dry, varnish with albumen; if you think it needful varnish over the albumen with photographic varnish. The process is more easy to work than to describe, and so certain that any amateur may work it more successfully than with glass alone. The tone of the pictures is a warm mellow neutral, soft and well suited to portraiture. With a well blackened paper boldness may be obtained, which would render it useful for persons in trade wishing to transmit pictures by post. The few specimens I took in summer are still fresh and clear.

I have also tried negatives obtained by collodion on white paper. The results as yet imperfect, but such a process is scarcely needed, as the calotype process supplies all that is required. A little might be gained in point of sensitiveness perhaps, and I fancy a dry process, positive or negative, might be formed upon this process. I may add that papers stained black by any other than a silver stain, give dirty pictures. They would answer, although imperfectly, when varnished in the hands of photographers who are not particular about their baths. I am, sir, your constant reader,
ZAFFAR.

P.S.—In your treatise on "Photographic Chemicals, their Manufacture," &c., will yot tell us how to convert silver ore into nitrate. I have a goodly lump, which would be handy.

[It must be borne in mind that any experiments in this direction will have a tendency to derange the nitrate bath from contact with the albumen, it will be wise, therefore, to keep a separate bath for the purpose, as in the collodio-albumen process. We can readily conceive that the blackened silvered paper will have an effect in giving vigour and sensitiveness. We do not see any reason, however, for fixing the paper prior to using, as that operation would be effected at the same time the positive was fixed in cyanide. We shall not be able to devote much space to the production of the salts of metals from their ores; but may possibly give you some hints on the subject.—ED.]

PHOTOGRAPHY ON WOOD.

36, *Porchester Terrace, Jan.* 21, 1861.

SIR,—I hope you will allow me to say a few words in answer to a letter from Mr. Thomas Bolton, contained in your last number, referring to an incident which happened at the meeting of the Photographic Society on the 15th instant.

Two proofs from a wood-cut, accompanied with a wood block, bearing a positive photographic impression, and *not* engraved yet, were submitted to the meeting, with a letter from Mr. Leighton, mentioning Mr. Bolton's name only with his, and the necessary inference would be, that the photographic transfer on the wood block was their joint production, or, at any rate, the work of one of those gentlemen.

Mr. Bolton in his letter states, that the transfer photographs I made on wood for Mr. Leighton "were so imperfect that they could not be engraved, and had to be erased to give place to the same designs printed by his process, and that he, Mr. Bolton, is the first to have carried the process to a successful issue."

I happen to hold a letter from Mr. Leighton, in which he acknowledges the value of my invention—saying, that I am the first to have transferred photographs for him on wood, in this country, with success.

Mr. Leighton adds, that he did not mention my name in connection with the block done by me, which he was exhibiting, as "*he thought, I would not be proud of it*;" yet, he seems to have thought the work good enough to pass under his own name, otherwise—and putting the mildest construction upon the matter—Mr. Leighton failed, totally, in common courtesy, in exhibiting to a professional assembly, without my knowledge, a work of mine, which, he thought, "I ought not to be proud of."—I remain, sir, yours sincerely,

F. JOUBERT.

[Whilst not doubting the *bonâ fides* of Mr. Bolton in regard to the blocks actually engraved, we cannot refrain from here again expressing our conviction, that the uncut block exhibited at the meeting of the Photographic Society, was the one executed by M. Joubert's process, and seen in his atelier, by Mr. Warren De la Rue, and ourselves, and that the fair assumption was that the engravings were, therefore, executed from similar impressions.—ED.]

ON COAGULATED ALBUMEN.

IN the last number of your journal "G. P." comments upon remarks made by myself in connection with the enquiry as to whether the sensibility of a Taupenot plate is attributable to a structural or chemical change produced in the albumen film, by the aceto-nitrate bath. After referring to the erroneous ideas which he conceives to be existing respecting the coagulation of albumen, he proceeds to state that when albumen is heated to 165° it coagulates into a white solid mass. The idea that I have hitherto entertained has certainly been that if undiluted albumen be heated to the temperature of 146° to 150° Fah., coagulation will ensue; if this be an erroneous opinion, it is one shared by Brande, Fownes, B. Bruce, Jones, Hoffmann, and others. When the albumen is mixed with a large excess of water, it is true that the coagulating point will be materially raised, but not when the former is diluted with only twice or thrice its volume. To decide the exact temperature at which a mixture of albumen water and iodizing salts, as usually employed in the Taupenot process, will be converted into its insoluble state, I made the following experiment:—I diluted one ounce of albumen with two drachms of water, and dissolved therein 6 grains of iodide of potassium, and 2 grains of bromide of ammonium. The temperature to which the mixture could be raised without exhibiting any indication of change was 146° Fah., complete coagulation occurred between this and 148° Fah. In performing the experiment I took the precaution of heating the solution with as much uniformity as possible. Heating from below alone necessarily causes a material difference of temperature in different parts of the fluid operated upon. I cannot but conclude from the above, that an erroneous idea in connection with coagulation of albumen exists in the mind of your correspondent. In the next place it is a familiar and well known fact that albumen can be dried without coagulation, and that in this state it is "a pale yellow brilliant gum-like substance, destitue of all traces of crystalline structure. The dried white of egg may be exposed to a heat of 212° without any alteration of its properties. When put into slightly warm water it softens, and at length in great measure dissolves. When reduced to fine powder, and washed upon a filter with cold water, common salt, sulphate, phosphate, and carbonate of soda are dissolved out, together with mere traces of organic matter, while a soft swollen mass remains upon the filter, which has all the characters of pure albumen obtained by precipitation." (Fownes). To obtain, however, this soluble albumen, it is imperatively necessary that the water should be driven off at a lower temperature than that requisite to produce insolubility. In my experiment the albumenized plate was heated and dried simultaneously at 180°, so that both the structural and chemical properties of the film must have been altered by the process of coagulation. That the thin layer of albumen resting upon a collodion film can thus be entirely converted into its insoluble condition, may fairly be questioned; that it is partially so, I have no hesitation in believing. The views of your correspondent with regard to the inutility of having two sensitive surfaces, one under the other, as in the Taupenot process, the lower one being of no use except to complicate the process, as the image is on the albumen and not on the collodion, is diametrically opposed to extensive experience upon the subject. The sensibility of the iodized albumen is found to be considerably augmented by being super-imposed upon the collodion film, instead of resting directly upon the glass. In conclusion I may state that the practice of washing or diluting the free nitrate of silver from the surface of the plate, which, according to "G.P." rests upon erroneous ideas, is rendered imperatively necessary rather an account of obvious manipulatory and keeping requirements, than upon any theoretical or chemical necessity.

Jan. 22, 1861. THOS. SEBASTIAN DAVIS.

Photographic Notes and Queries.

INDIA-RUBBER FOR BATHS.

2, *Queens-sq., Westminster*, 12*th, Jan.*, 1861.

DEAR SIR,—It is somewhat surprising, considering the great want of a light, *unbreakable* substance to supply the place of glass and gutta-percha—the former for its unsuitable nature for travelling, and the latter for its non-resistance of chemical action. I say it is somewhat surprising that photographers have not given more attention to that very useful article, india-rubber; but I suppose it is attributable to the fact that they are more familiar with *vulcanized* india-rubber, which is *totally unfit* for use in photography, owing to the large quantity of sulphur it contains, but that generally known as best "stationer's sheet" is perfectly free from adulteration or foreign matter of any kind, and nothing is more suited to the present wants of photography than the *pure* gum, which has not the slightest action on silver solutions, or even on the most delicate solutions used in photography.

I most specially recommend it for baths and apparatus in general for *travelling*, from its extreme portability—a bath for whole plates, when *folded up*, being a convenient size for the waistcoat pocket.

How I arrange this, and how an amateur may make good and cheap travelling baths, &c., himself, I shall be most happy to communicate at some future period, and am, yours obediently.

LEO. DAFT.

Talk in the Studio.

NEW IODIDE.—The discovery of a new neutral and colourless iodide of starch, was announced by M. Duroy at a recent meeting of the French Academy of Sciences. It is well known that iodine gives a blue colour to starch, thus forming an iodide. M. Duroy brings this iodide into contact with yeast and thus deprives it of its colour. In this state it is very soluble in water, insoluble in alcohol, sweet, grummy and incapable of crystallization.

A NEW PHOTOGRAPHIC SOCIETY.—A society has just been formed in Newcastle-upon-Tyne for the advancement of photographic art and science, and is entitled the "Newcastle-upon-Tyne and North of England Photographic Society." The object is proposed to be attained by the reading of papers, experimental demonstrations, discussions, and conversations on all subjects connected with the art, and the exhibition of photographs, apparatus, &c. A society for the promotion of this delightful art, observes a provincial cotemporary, cannot fail to enlist a large amount of sympathy, and be productive of the greatest benefit. It already possesses a large number of members, and an active honorary secretary, Mr. J. F. McKie. From our knowledge of the general energy and indomitable perseverance of the men of this district, we anticipate that the society will prove a successful one.

HOW TO TAKE A FIDGETTY SITTER.—The editor of the *American Journal of Photography* tells a story of an artist "way down south in Dixie," who adopted a novel expedient to keep his sitter quiet. He had tried all sorts of suasions without success, when it occurred to him that the strongest of all human motives is fear. As soon as he had completed his adjuncts, he suddenly draws a revolver, and levelling it at the sitter's head, he exclaims in a voice with a look suggestive of lead and gunpowder: "Dare to move a muscle and I'll blow your brains out." The editor has not seen any of the pictures produced by this process, but has no doubt that they present some interesting peculiarities.

TOUCHING IN BLACK AND WHITE.—A correspondent forwards us the card of a provincial photographer, who, after announcing that he he has made arrangements for taking "portraits in miniature, (for brooches, &c.), also on canvass, and in every other style to which photography is applicable, in a manner superior to most, but inferior to none," proceeds to state that he "will continue to carry on chimney-sweeping as heretofore, and all orders shall be promptly attended to. The best machines kept, and contracts entered into."

IODINE IN RAIN-WATER.—M. Chatin informs the Academy of Sciences of Paris that he has found *iodine* in the rain-water of Pisa, Florence, and Lucia; and that although he had not succeeded in obtaining that element in its natural state from these waters, he had extracted it from two aquatic plants—viz., the *nasturitum officinale*, and the *ceratoppyllum demersum*, a fact which showed that the water in which they grew must have contained some.

INDIA-RUBBER PHOTOGRAPHY.—Mr. Fitzgibbon, an American photographer, writing from Guatemala to the *American Journal of Photography*, states that he has used india-rubber in the place of collodion. Sending specimens, he says—"the negatives were taken by a collodion, made of pure india-rubber-milk, ether, and alcohol, sensitized with iodide of ammonia, iodide of cadmium, and bromide of cadmium. The milk I obtain direct from the tree, and purify it by repeated washings in blood-warm water. The albumen paper was floated on a 140-grain to the ounce silver bath for five minutes; thoroughly washed in a weak solution of salt and water for about five minutes; toned in gold bath of proportion of ½ a grain to each of water—rinsed rapidly in water (say 30 seconds), and fixed in bath of 32 oz. water, 4 oz. hypo of soda, and 1 oz. acetate of lead. Washed afterwards in the usual manner. I find my india-rubber collodion negative turns dark and spoils after a few exposures to the sun; I am now experimenting with a view of obviating the difficulty."

REJLANDER'S PHOTOGRAPHS.—The *Athenæum*, noticing some of Rejlanders studies from life, says:—Six of these lying before us sustain the high reputation of the well-known operator. One of a young woman trimming her father's hair, and giving an unnecessary twitch to the old man, is noticeable for design and photographic success. "The Toilette," another, showing a young mother under the hands of an Abigail, while her child dresses a doll, is equally praiseworthy. For softness and truth of effect, the Wrestle studies from the nude, are admirable.

To Correspondents.

VOLUME IV OF THE PHOTOGRAPHIC NEWS.—In answer to several correspondents who have been disappointed in obtaining the volume complete, we have to announce that in consequence of the rapidly increasing circulation of the PHOTOGRAPHIC NEWS, several of the early numbers of the last volume are out of print. We are reprinting them as quickly as possible, and hope to have Vol. IV complete, ready in a few days.

PHOTO MINUS.—We shall possibly give some hints on the use of the oxy-calcium light at the conclusion of the articles on the oxyhydrogen light

M. U. D.—The best preparation that we know for the positive previous to applying oil colours, is a solution of isinglass in hot water, adding a little gin or spirits of wine after it has dissolved. It must be applied whilst warm, with a flat camel's hair tool. Let it dry spontaneously, and if necessary apply another coating. A little experience will teach you the proper thickness of the solution; it is better to use it somewhat thin and apply it several times, than to use it thick once, as in the latter case it is apt to crack off. We have found this an excellent preparation for our own use. The dirty yellow tint of which you speak arises from the oil coming to the surface, and in time turning horny. Use as little oil or vehicle with your colour as you can conveniently work with.

HENRY COOPER, JUN.—Your plate had probably been exposed to light between the application of the gallic acid solution and the pyrogallic solution, which would, on the slightly depeloped plate, produce, under certain conditions, the effect of a direct positive, whilst the fully developed plate would not be affected.

F. U. S.—The cement for glass we prefer for our our own use is marine glue, Shellac dissolved in alcohol answers for some purposes. You will find a good deal of information on the subject in our third volume, in treating of joining glass in the series of articles, "The Amateur Mechanic," and in other articles on the subject.

A FEW AMATEUR SUBSCRIBERS.—We strongly suspect from your description that the collodion is in fault and not the bath. If you put away a bath in good working condition in a chemically clean bottle, it ought, unless it has been tampered with, to work when next required. If, as you state, you could not get a trace of an impression, the faults more probably arose from insensitive collodion and under exposure, than from any other cause. All simply iodized collodions, in which alkaline iodides have been used, lose sensitiveness by keeping; as to the collodion of the maker you name, we have frequently had complaints of its rapid loss of sensitiveness. Use a collodion containing a bromide as well as an iodide. The method of correcting a bath to which you refer, we have always found perfectly efficacious. Do not readily despair. Where others have succeeded you may succeed Remember the child's song:

"All that other folks can do,
You by trying, may do too,
Try again."

THOMAS BARRETT —There appear many points of similarity between the apparatus invented by M. Pallu, described in our last, in the article "Photography without a Camera," and your portable camera, described at pp. 79 and 90 of our first volume. We recommend the attention of our readers interested in the subject, to read again the description of Mr. Barrett's camera in our first volume. We shall be glad to see yours, if convenient to you. We will communicate further by letter.

A. S. L.—Dallmeyer's new instantaneous stereoscopic lens is not intended to cover a quarter plate. It will, however, cover a plate 4 by 3, and answers admirably for portraits of that size.

R. C. B B. J., India.—In our next.

E. A. H —The wet process will present the fewest difficulties, and you will find it well to acquire facilities in taking negatives by the wet process before commencing to prepare dry plates. You will find it easier also to acquire that familiarity in your glass house than in taking views. In regard to your questions. 1. Coat the plate with negative collodion. 2. Use of bath of 35 grains of silver to one ounce of distilled water, as nearly neutral as will work clean. 3. Develope with pyrogallic acid 2 grains, citric acid 1 grain, or pyrogallic acid 2 grains, acetic acid (glacial) 15 minims; or protosulphate of iron 10 grains, acetic acid (glacial) 15 minims, and strengthen with one of the former developers and silver. 4. Fix with hypo and be careful to wash well. 5. If you require many prints always varnish the negative; if not, please yourself, use a hard spirit varnish. 6. Unless you require a large number and have not much time, print yourself. 7 Albumenized paper, which, as you have but little time, you had better bring ready prepared. 8. Sensitize by floating on a 60 grain nitrate of silver bath, and take care to keep up the strength, as it will diminish fast by use. See a paper on this subject by Mr. Hughes which will shortly appear in our pages. 11. Tone by the alkaline gold toning bath, and after fixing, wash very thoroughly with repeated change of water during about 12 hours. See PHOTOGRAPHIC NEWS ALMANAC for much of the information you require.

J. T. R. W.—If you use neutral chloride of gold, the addition of phosphate of soda is sufficient as given in Maxwell Lyte's formula. As, however, much of the commercial chloride of gold contains free acid it is best to neutralise it at once, by adding to the solution of fixed strength, sufficient carbonate of soda to render it neutral to test paper. From 2 to 5 grains of soda will generally be required for each grain of chloride of gold. About 15 minutes is generally sufficient time for prints to remain in the hypo. Some judgment, however, must be used, as much depends on the strength of the solution and the thickness of thespaper Thin paper is most quickly fixed. See announcement above regarding our 4th volume.

MARY.—You will find some information on enlarging in the PHOTOGRAPHIC NEWS ALMANAC, and we shall shortly have some articles on the subject. It entirely depends on the focus of your lens, and the length of your camera when extended, as to whether you can make your present appliances useful. If your quarter-plate portrait lens be about five inches focus, which is the usual length, your 9 by 7 camera will require to extend about 20 inches in order to enlarge stereo to the size you wish.

J. ANDREW is thanked for the curious document, which will appear in the column referred to.

AN ASPIRANT —A method of photographing on ivory will shortly appear in our columns.

Mr. RICHARDS on the albumen process will be given in our next

J P, R W R., Prendergast and others in our next.

MAJIC LANTERNS.—Several correspondents are thanked for their communications which will appear in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 126.—February 1, 1861.

WHAT IS A VARNISH?

This question is not so readily answered as may at first appear. In general terms, it may be defined as the solution of a resin in a suitable menstruum. This vehicle may be oil, or turpentine, or alcohol, chloroform, benzine, or other volatile liquid. The quality of a varnish must depend upon two things:—1st, on the nature of the resin or resins of which it is composed; and, 2nd, on the nature of the solvent.

First we examine the resins, not *gums*, as they are frequently called; gums are soluble in water, resins are not; gum arabic may be taken as a type of the gums, the solution of which in water forms *mucilage;* amber may be taken as a type of the resins, the solution of which, in a fixed or volatile menstruum, constitutes *varnish*.

The resins are hard, like copal, amber, and lac or brittle, like mastic, sandarac, or dammar;—or soft, like benzoin, elemi, anime, and the viscid turpentines, as Canada balsam.

The quality of the resin determines the physical characters of the varnish; for, as the solvent evaporates from its solution of the resin, except in case of oil, it must necessarily leave the resin in the state it was before being dissolved, consequently, a brittle, friable resin will never make a tough, hard varnish, and *vice versâ*. Hence, in order to estimate beforehand the suitability of a resin for a varnish adapted to a given purpose, it is necessary to examine its quality before being dissolved.

But the choice of the solvent is not arbitrary; certain resins require particular solvents; thus hard E.I. copal. is most readily dissolved in boiling linseed oil; so also with amber; these resins are scarcely soluble in turpentine, even under special elaborate treatment; they are not at all soluble in alcohol or ether, and amber is only partially soluble in chloroform. Mastic and dammar are soluble in turpentine, and partially so in alcohol.

It may happen that the qualities desiderated in a varnish are not furnished by any single resin, therefore it becomes necessary to add to it others which supply the deficient quality. Thus, to a resin which is too hard and brittle we add another that is soft and plastic; the compound is neither too hard nor too soft, but offers both sufficient tenacity and resistance.

When a resin is dissolved in oil, the oil in drying, as it is called, becomes oxydized, by absorbing oxygen from the atmosphere, and is also converted into a resin. In this kind of varnish the resin is greatly modified by the solvent. Turpentine generally retains some resinous matter in solution, which combines with the resin dissolved in it, and also modifies it, rendering it less easily drying, *tacky*, as it is called. Camphene, which is a highly rectified turpentine, evaporates without leaving any residue; it is, therefore, preferable to turpentine as a solvent of many resins.

If the solvent be too volatile, the varnish cracks in drying; for the solution spread out thinly over a large surface, suddenly loses a portion of its constituents, and the contraction not following the evaporation sufficiently quick, the varnish dries in detached patches, the intervals between them constituting the cracks. Cracking of a varnish may occur when, applied to a film, as collodion or albumen, it dries quicker than the film, and the unequal contraction tears the film into patches. Benzine, ether, and chloroform are, for this reason, objectionable as solvents, unless mixed with alcohol; although alcohol evaporates readily, it does not do so rapidly enough to cause the varnish to crack.

Heat aids the solvent power of the menstruum. Thus, to melt copal or amber, it is necessary to employ the linseed oil in a boiling state, which is a very high temperature, nearly 600° F.

Of all the substances proposed for photographic varnish, white lac dissolved in alcohol appears to possess the largest share of good and indispensable qualities. But it requires much skill and experience to ensure success in its manufacture; the addition of benzoin is thought to effect an improvement in it, by rendering it less brittle. Benzoin itself, freely soluble in alcohol, presents a ready substitute for lac varnish, but it will not endure such rough usage.

The subject to be varnished should be throughly dried before a clear fire, and the varnish warmed also. The presence of moisture produces the effect called *chill*, or *bloom*.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Agreement.—That natural and artful union of parts which gives force and power to the resulting whole. A picture's leading characteristics should influence all its parts, otherwise it runs counter to the laws both of nature and art. The law of agreement is frequently overlooked in what is termed "composition" photography, and it is by no means uncommon to see in a picture printed in from several negatives the most glaring inconsistencies. These more frequently arise from the fact of different figures, or portions, having been taken at different hours of the day, or when the light has changed in its nature. In a group of figures, &c., thus obtained, it is by no means uncommon to see the dark shadows of a weak light, and the weaker shadows of a strong light existing where but one light is supposed to illuminate the whole. There is much danger also of obtaining a similar defect from the unequal amount of intensity displayed in the different negatives; an undue depth of the shadows or strength of the lights in one negative giving qualities which may disagree with those of a differently developed or less exposed negative, thus destroying the truthfulness of effect and agreement of the whole, to the utter destruction of keeping and harmony.

Agreeable.—When a picture represents one of a class of subjects which are not very elaborate in their nature, and which do not contain any of the more refined subtleties of expression, or very great depth of meaning, it is usually described by this term as being opposed to the more lofty and grand of pictorial styles. With such subjects photography has dealt with far more success than can possibly reward its more ambitious efforts, and it were well in a general way not to aspire beyond the bounds thus indicated—within which the photographers' ambition may find ample scope for his best efforts, no lack of difficulties, and the largest share of promises.

Aim.—Every work of art should be governed by some particular aim or intention with which all its parts should be in keeping, and which should never be lost sight of during the various stages of progress. In photography, the choice of light, and of view, the exposure and development, the printing and the toning, may each and all be rendered subservient to some one aim or intention in connection with the general expression or effect.

Allegory.—A composition figuratively expressing something apart from that really represented. Photography has dealt with these subjects; and, in the hands of our very talented contemporary Rejlander, with no small success. Allegorical pictures should at once convey their real meaning, although their apparent subject should never be so closely connected with the real as to make the latter too obvious. Allegory has been compared to a crystal covering an object, although not concealing it; and it is usually represented in sculpture as a female vainly attempting to conceal herself within the folds of a transparent veil. Simplicity is a very valuable quality in an allegory.

Anamorphosis.—An eccentric piece of perspective which gives the effect of extreme distortion. It will arise from choosing a point of view injudiciously, or too near the object. Such results are very curious and amusing when secured for the stereoscope; and sometimes puzzle the amateur photographer, who, while conscious that such strange effects must be perfectly true, is at a loss to account for their distorted and eccentric appearance. The position of the camera in reference to the object is of the utmost importance in order that you may avoid representing an *anamorphosis.* It was the custom with teachers of perspective to illustrate this point by exhibiting a drawing monstrously deformed when seen in the ordinary position, but symetrical and truthful enough when placed in a certain unusual position, or viewed in a cylindrical mirror. Anamorphosis may be sometimes described as the quality of fore-shortening pushed to an extreme. Further information on this subject may, however, be procured from any work on optics.

Anacamptics.—A term indicating the theory of reflected light, which the photographic student will do well to make himself acquainted with: reflected light being one of the most important of his pictorial agencies.

Anaclastics.—The doctrine of refracted light.

Animated.—Applied to the successful indication of life in a picture. The artist does not understand by this mere perfection of detail in reference to form, or light and shade, but that which indicates vigour and general truth of effect, more especially with regard to action and expression. For such a quality, therefore, the photographer must study, say, the pose selected, in order that it may harmonise with, and lend force to the expression of his model's countenance. The eyes and mouth may vigorously express lively and active thought, but if the poor tame pose be one which has no agreement with such expression, the whole effect will be lost, which otherwise might well deserve the praise and secure the perfection implied in this term *animated.*

Antiques—No branch of our art possesses such real value as that which is devoted to the reproduction of the ancient specimens of classical or high art recognised under this term. With this idea the Greeks are most closely associated, inasmuch as the beauty, truthfulness, and grandeur of their productions are so generally admitted as to constitute the modern artist's ideal types of perfection. To reproduce such types in all their glorious qualities, with unerring faithfulness, and to circulate them through the whole world of art, refining the popular taste and cultivating the popular judgment, is surely a lofty and ennobling mission. If in so doing no object was served beyond the mere preservation of relics of such great and enduring interest, photography would still deserve our warmest gratitude. Such majestic works of art are even now in their distant lands crumbling into decay, or are being far more speedily destroyed by the almost daily devastation of tasteless but curious travellers, and ignorant natives, so that it is very probable that photography may soon have preserved to us the only remains of many such mighty productions. The statues which Phidias executed for Pericles; the works before which, 2,500 years ago, Plutarch stood and gazed with admiring wonder, or portions of those temples in which the most civilized and refined of ancient nations worshipped their poet-created gods, are brought by the aid of photography into the homes of our very humblest art-lovers, and preserved for generations yet to come. The study of the antique is regarded by artists as the most essential branch of their education, and photography may prove of great value in simplifying and accelerating such studies; or placing its means within the grasp of hundreds of poor aspirants for the painter's honours, from whom, without such aid, these means were hopelessly removed.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analylsis.

Having given the best methods of preparing nitrate of silver from silver coin or plate, we think it will be as well to devote a little space to describe the best means of working up and converting the photographer's silver residues into a useful form. Usually it is recommended to keep several different receptacles for these residues—one for old baths, another for waste developing solution, another for exhausted fixing solution, &c. This may be all very well for those photographers who are in the practice of using up nitrate of silver by the pound or two at a time; but for the more numerous class, who deal with that expensive chemical by the ounce, we think that the plan of separate vessels and different treatment for each batch introduces more trouble and complication than the silver saved is worth. It must be remembered that it takes but a little more time to work up several pounds of material than it does a few ounces, and it may be well worth a photographer's time to devote half a day to extracting some pounds of silver from his waste solutions, when it would not pay him to devote that time to recover merely an ounce or two. We, therefore, advise, as the result of a pretty long experience in such matters, that all the solutions, whether baths, hypo, developing solutions, or anything else which may by any possibility be supposed to contain silver, be thrown into a large stoneware jar, of at least two gallons capacity, and having a wide mouth. This should stand in one corner of the operating-room, and all the washing waters, and wash developing and fixing solutions, poured from collodion plates should be allowed to run into this jar. As the jar soon becomes filled with the accumulated solutions, steps should be taken to precipitate the silver from it, and syphon off the clear supernatant liquid. For this purpose procure some *hepar sulphuris* (liver of sulphur, or polysulphide of potassium) which may be purchased at the chemists, or made by fusing together in a crucible two parts of carbonate of potash and one part of sulphur; dissolve it in about six times its weight of water, and when the jar is nearly full of residues add some of this solution to it until there is no longer a black precipitate produced. Allow the mixture to stand for about twenty-four hours, and then, having first tested the clear liquid with some of the sulphur solution, to make sure that all the silver has been removed from it, syphon or decant off the clear portion and throw it away, leaving the black sediment at the bottom. Now accumulate more residues in the jar, and repeat the operation of precipitation and removal of the clear liquid, until the black sediment has accumulated to such an extent that little room is left for any more solution. The sediment, which will consist for the most part of sulphide of silver, mixed with a little sulphur, must next be separated from the liquid and dried. For this purpose nail a piece of fine calico to wooden cross bars, so as to leave a hollow bag hanging down to form a filter; rest it on a convenient support and, after having well wetted it with water, pour the thick, black mud into it. Perhaps the first portions which come through may not be quite clear, if so return them to the filter till the filtrate is no longer turbid. The preliminary wetting with water is for the purpose of expanding the fibres of the calico before the thick mass comes in contact with them, otherwise they would expand around the particles of sulphide of silver, and the pores would be almost closed up and the filtration retarded.

When all the sediment has been placed on the filter, wash it once or twice by pouring common water over it, and then allow it to drain for some hours, and afterwards dry it in an oven on a plate. When dry it is ready for being reduced to the metallic state, which may be effected in the following manner:—

Fill a Cornish crucible with nitrate of potash, and place it on a good coke fire until it melts to a clear liquid, and the bottom of the crucible shows signs of becoming red. Then, having previously well powdered the black sulphide of silver, shake a little at a time into the melted salt by means of a spoon or the point of a knife. As each particle touches the melted nitre it will apparently dissolve in it with violent effervescence, and evolution of intense heat and light; too much must not, therefore, be put in at a time, or there will be risk of explosion. When the action appears to become sluggish, increase the heat a little in order to render the contents of the crucible, which will have now become pasty, liquid, and then, taking hold of the crucible by means of a pair of tongs, pour the contents out on to a clean iron plate. Replace it in the fire and fill up with fresh nitre, and continue projecting sulphide of silver into it until it is all used up, pouring it out each time the action appears to be slackening. Soon after the fused mass has been poured out on to the iron plate, and before it has had time to get cool, place it in a vessel of clean water, and let it digest there until the soluble portion has dissolved away, when metallic silver will be left behind, either in the form of a light, spongy mass, or fused globules, according to the temperature which has been employed. Well wash it by boiling in distilled water two or three times, and then dissolve in nitric acid, as recommended in previous chapters.

In the case of waste paper cuttings or filters, rags, &c., which may have any of the precious metal upon them, they should be burnt in a crucible, and the ashes thrown into fused nitrate of potash, as recommended above in the case of the sulphide.

One or two enquiries have been made us respecting the mode to be adopted in converting native silver ores into nitrate of silver. The most convenient plan will be to powder them, or if that is not practicable, to break them up into as small pieces as possible, and then to throw the powder into melted nitrate of potash, in the manner recommended above. At the end of the operation the temperature should be raised to a bright red, or full yellow heat, and kept so for ten minutes or so. The mass then poured out and extracted with water, will leave metallic silver. As however, ores seldom consist of their ingredients in a state of purity, and as silver ores may contain copper or other metals, which would prove injurious if allowed to find their way into the nitrate of silver, it will be safer to dissolve up the crude silver obtained in this manner in nitric acid, and precipitate the metal from the solution by means of copper. The reduced silver can then be dissolved up into pure nitrate, as previously recommended. If, as is almost always the case with photographer's silver residues, gold is present with the silver, the whole of this will be left behind, in the form of a dark powder, when the silver is dissolved in nitric acid. It should be filtered off, washed, (at first with a little dilute ammonia, to free it from any chloride of silver which might be present,) and then dried and placed along with the metallic gold accumulated in former experiments, until the quantity becomes sufficient to work up into chloride, or sell to the refiners. We must not omit to state here, that both silver and gold being articles of commerce, can always be sold for their real intrinsic value, the photographer may frequently prefer, after having obtained his lump of metallic silver, to sell it and purchase pure nitrate with the proceeds, in preference to being at the risk and trouble of converting it into nitrate himself. He will merely have to take the lump to a respectable assayer, where it will be weighed before him; in a few days the assay will be finished, and a paper showing the results of the assay, and the market value of the silver, less a small sum (6d. we believe) for the assay, will be handed to him. He is then at liberty either to take the lump of silver away again, or the money, whichever he pleases; silver prepared from residues in the manner recommended at the commencement of this chapter should always be commercially pure, and will fetch 5s. 2d. per ounce. In most cases photographers will find this the most economical plan of converting silver into nitrate—it is certainly the least troublesome.

HOW TO ASCERTAIN THE AMOUNT OF SILVER IN A NITRATE BATH.

With Remarks on Argentometers and Bath Testers.

BY C. JABEZ HUGHES.*

The purpose of the present paper is purely practical, and bears reference to one I read at this Society about twelve months since. I then expressed my belief that many of the faults of albumenized prints arose from having the sensitising solution too weak, and recommended the use of a little instrument known as the silver-bath meter, based on the principle of the hydrometer, to insure that the silver solution should never be employed below a known strength. I recommended the instrument then, not as a perfect one, but as very simple, easily managed, and sufficiently accurate for the *printing* solution.

Since then I have heard it often spoken of depreciatingly, and even denounced as leading *only* to false results. As I am not aware that any body has gone through experiments to ascertain how far it is right or wrong, or of comparing it with other instruments for accomplishing the same object, and being still convinced that I had derived much benefit by its use, I determined to make a series of experiments to satisfy myself of its exact value. Understand me, I am not the inventor of this instrument, I did not bring it out—I do not know who did, and am its advocate only so far as I believe it to be useful in aiding the production of good prints.

Many methods have been proposed to ascertain the amount of silver in any aqueous solution. They are nearly all based on changing the soluble into an insoluble salt; one method judging by the quantity of precipitate produced, the other by the amount of material required to cause the complete precipitation.

The silver may be thrown down as a chloride, cyanide, sulphuret, oxide, or metal; but from the nitrate solution it is most readily treated as a chloride.

When a perfectly accurate result is required—a nitrate solution being under examination—it must be strongly acidified with nitric acid, and pure hydrochloric acid added till all precipitation ceases. After well shaking let it settle for some hours; decant, and wash the precipitate well and carefully with distilled water. Do this many times, till the last water ceases to redden litmus paper, then decant, evaporate, and fuse the chloride; finally, carefully weigh, and the amount of nitrate of silver contained in the quantity of solution can be inferred from the amount of chloride obtained, allowing 3½ grains of the nitrate for every 3 grains of chloride; the exact proportion is 3 of the former to 3·555 of the latter.

This method is theoretically correct, and if perfectly conducted must lead to exact results. It is, however, far too troublesome and lengthy for our daily wants, and requires a person to be acquainted with chemical manipulation.

A much readier method is based on the principle that, as there is only a limited quantity of silver in any solution, if we can know how much chloride is required to precipitate it, we can from that infer the quantity contained. This saves all the trouble and time of collecting, washing, drying, and weighing the precipitate.

Many applications of this principle have been published. Mr. Heisch read a paper sometime since, at the Blackheath Photographic Society, which was published in the journals, in which he showed how silver can be estimated to the hundredth of a grain per ounce solution.

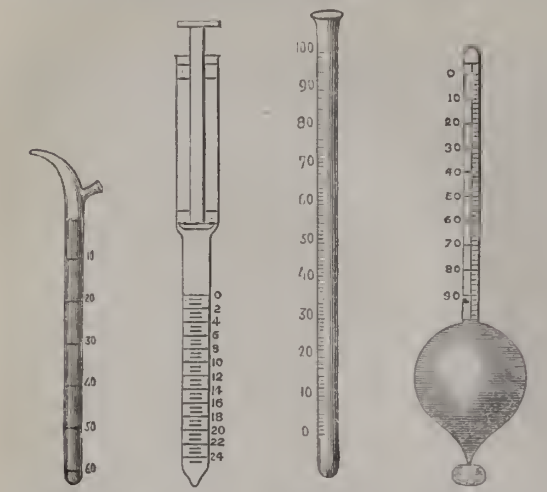
In the Appendix of Mr. Hardwich's "Photographic Che-

* Read at a meeting of the North London Photographic Society, Jan. 30th.

mistry," another method is given, accurate to one grain, or even half a grain, per ounce.

These methods are based on making standard solutions of certain exact strengths of pure chloride of sodium, and, according to quantity required to cause precipitation, is calculated the amount of the silver. These operations require to be most carefully conducted, or correct results cannot be obtained.

To obviate the trouble of calculation, certain instruments have been invented, graduated to scales suitable to certain standard solutions, to be used with them.



Wood's Argentometer.* Hockin's Argentometer. Horne & Co's. Bath-tester. Hydrometer Silver-tester.

Mr. E. G. Wood's argentometer is a glass tube, graduated from 0 to 60, which he fills to 0 with a standard solution of pure dry chloride of sodium 33 grains, distilled water 13 ounces 1½ drachms. Into a measure glass is placed a drachm of the nitrate bath, into which the saline solution is poured from the graduated tube. A dense white precipitate of chloride of silver instantly falls. The standard solution is added until the last drop or two causes no more precipitate, when the quantity of the solution used from the graduated tube shows by the number of the division at which it stands how many grains per ounce of nitrate the bath contains. Thus, if 30 divisions of solution are used, the bath contains 30 grains; if 40 divisions, 40 grains, and so on.

Mr. Hockin has devised another form, a graduated syringe, It is used with a standard solution of pure dry chloride of sodium, 69 grains (68, 94) in 1000 minims (2 ozs. 40 minims) of distilled water. In using, one or two drachms of the nitrate bath are to be added to an equal bulk of nitric acid and twice or thrice the amount of distilled water. Fill the instrument to zero, by slowly raising the piston, the point being kept under the test liquor. Depress the piston and cause the saline fluid to pass into the portion of bath prepared as above, vigorously stirring all the time. A heavy white precipitate of chloride of silver takes place directly. The solution requires well stirring, and the standard fluid added till only an opalescent appearance remains, and when, after drop by drop being used, no more precipitate is formed, the operation is complete. The number of graduations left empty indicates the number of grains of nitrate contained in the quantity of solution examined.

Messrs. Horne and Thornthwaite's bath tester is a graduated tube marked from 0 to 100. They employ a standard solution, pure dry chloride of sodium 84¾ grains in 20 ozs. distilled water.

* We observe at the last moment, when it is too late to remedy it, that the engraving of Mr. Wood's instrument is on a somewhat smaller scale than the others.—Ed.

To use, fill up to 0 with the nitrate bath to be examined, then gradually add the test solution, shaking violently between each addition. When no more precipitate is produced, the number of graduations at the top surface of the fluid, shows the number of grains to the ounce of nitrate of silver contained in the solution examined.

The other instrument I introduce professes to estimate the strength of the nitrate of silver solution on the principle of the hydrometer.

It has only to be immersed in the solution, and the number on the stem of the tube, where the surface of the solution intersects, shows the supposed number of grains of nitrate of silver contained in each ounce.

With a view to form a correct estimate of the value of these instruments, I undertook a series of carefully conducted experiments upon five different nitrate solutions. I may mention that so important did I consider these experiments, and so anxious was I to avoid error, that I asked the assistance of a gentleman of undoubted qualifications, Mr. G. Wharton Simpson, who kindly gave me the best part of one day to assist in verifying and working them out.

These experiments were performed with great care. Pure, well dried chloride of sodium was accurately weighed and dissolved in distilled water as directed.

Of the five solutions of nitrate of silver tested, two we made up ourselves, one ten grains the other thirty grains to the ounce, and being tested directly they were mixed, no foreign substances were present to influence the result. Another solution was a portion of a bath used for albumenizing paper, which was mixed, I cannot tell when, certainly some years since, and has always been receiving additions of nitrate of silver and distilled water, and was, therefore, an extreme test. A 60-grain solution of port wine colour I obtained from one of our Regent-street photographers. It had been used to sensitise only a few sheets. Another bath tried was one made up about four months since, and has been constantly in use for sensitising collodion plates, negatives and positives. Here are the results as shown by the different instruments:—

	Hydrometer Silver-tester.	Wood's Argentometer.	Horne & Co's. Bath-tester.	Hockin's Argentometer.
New 10-grain bath	10	11	12	12
New 30-grain bath	30	31	29	31
60-gr. bath, port wine colour	60	61	60	62
Old albumenized paper bath	56	56	54	56
Collodion plate bath	16	25	23	25

It will be seen from the above experiments, that where the exact strength of the solution was known, that in only one instance did a "standard-solution" give the precise strength, they generally indicating one or two grains over or under.

That there should be such variations is only reasonable, for unless the most scrupulous care be taken, many errors may creep in. The chloride of sodium may not be quite pure or dry, and the graduated measure not quite accurate. Then the minim glass, with which the drachm of nitrate bath is measured, may not be graduated very perfectly, and we know in commerce how they vary; there is also the risk of putting in too much of the test solution at he very last, to ensure all the nitrate being thrown down; all these are sources of error which are always more or less present when these instruments are in the hands of the general public. Again, as there is only a drachm of the nitrate solution experimented on, from which to infer the quantity contained in the ounce, it is clear that if there be an error it is magnified eight times.

It is hoped these remarks will not be considered as depreciatory of these useful and ingenious instruments, as they are only intended to show the great care necessary to prevent obtaining false instead of true results. In our experiments we might have used graduated glass measures that had been verified by standard ones, but we felt this unnecessary, as we wished to place ourselves in the position of an ordinary operator, and, therefore, employed the usual well-made, graduated glass measures that are supplied by respectable houses.

If proper precautions be adopted, our impression is that these instruments may be relied on for giving within about two grains, either over or under, the exact amount of the nitrate contained in each ounce of solution. In our experience they appeared to rather over-estimate the amount. We do not feel at liberty to say which is the best of the three, as they are all different, and have each a merit peculiar to itself.

Messrs. Horne and Thornthwaite's does not require any additional graduated measure for the drachm of nitrate solution to be examined, by which one source of error is removed. Mr. Wood's is very neat and elegant, and the result very easily read off. He has two forms, and we used the cheaper one. Mr. Hockin's graduated syringe is theoretically, perhaps, the most perfect; and when a person has got used to it he may work it very exactly, but we fancied if the standard solution was less concentrated, or the graduations made wider, it would be an improvement; but we have only to repeat, they are all very ingenious, and do their work without giving the trouble of calculation. They are equally applicable to the bath for sensitising collodion plates and albumenized paper, but must not be used in solutions containing cyanides or hyposulphites. The other little instrument, based on the hydrometer principle, when tried in new solutions of known strength was found to be *absolutely correct*, and on the very old printing solution, which was the real practical text, it corresponded with two out of three of the standard solution tests, and only differed two grains from the third.

The principle on which this instrument is constructed, the increased weight communicated to water by the addition of nitrate of silver, is quite hostile to the introduction of such light fluids as ether and alcohol, and as the bath for sensitising collodion plates always contains these, it was hardly necessary to try it in our old bath used for this purpose. Still as we tried the other instruments we tested this, and, as we supposed, it did not register correctly, showing much less nitrate of silver than the bath contained. This instrument, then, is not fitted for solutions of this character; but, as the errors are only on one side, even this peculiarity may occasionally be useful, for *it never can register* MORE *nitrate of silver than the bath contains, always less.*

Speaking generally, then, this instrument is less perfect than the others, because it is applicable to only one of the two photographic silver solutions; but for that one it answers admirably, and may be depended upon even more certainly than the others; and as this solution, the printing one, is the one that is daily required to be tested, the little instrument should be considered as peculiarly fit for it, and it only.

I began these experiments without the knowledge of the degree of accuracy of these argentometers. I determined to test them all carefully and strictly, and to record the results impartially. I am happy to bear testimony to the usefulness and practical approach to perfection of the gentlemen's instruments whose names I have mentioned. With respect to the other instrument I confess I had many misgivings of it, for one cannot avoid being influenced by frequent condemnations, and I am agreeably astonished at its great accuracy in its more limited vocation. That it fails in the presence of ether and alcohol is what every intelligent person would have surmised.

I think, therefore, that each of these instruments should have credit for what is due to it, and that every photographer should have one of each; the standard-solution one, for testing his collodion bath, which he should do himself, say once a week, with all the precautions against mistake already named; and the other for his assistant or printer to be used daily, for he has only to immerse it and the strength of solution is told.

After rendering due justice again to the useful and ingenious instruments I have named, I yet feel justified in again recommending the hydrometer silver-tester for ascertaining the strength of the silver printing solution, and conclude with the words I used about a year since: "the merit of this little instrument is its simplicity. Without professing analytical accuracy, or the perfection of more complicated instruments, it is sufficiently correct for all practical printing purposes, and no knowledge of chemistry is required for its use. It is always ready, needs no calculation, and the dullest boy can employ it."

Photographic Notes and Queries.

ALBUMINATE OF SILVER FOR FOTHERGILL PLATES.

SIR,—Experimental photography being just now so much practised, perhaps some of your many readers may feel inclined to test a new method (new to me at any rate) of introducing the albuminate of silver in the Fothergill plates, I have only tried 2 or 3 small plates, but find they are as sensitive at least as the old ones, and with greater rapidity of development, I think. I do not intend to say that they are an improvement on the original manipulation, for I have not experience enough to fully test that. I make a collodion plate sensitive in the usual way, well wash in four waters, and pour over it this prepared albumen, (Fothergill albumen 2 drachms, water 6 drachms, a few drops of bath solution dropped into it, and shaken up, when, if the silver has not been added too liberally, it will redissolve the precipitated albuminate), drain the plate ten minutes or so, and dry, which completes its preparation. The first plate I prepared I tested by this means: I laid on it an opaque disc, and put it under a fish-tail burner for a few minutes, when on removing it I plainly saw the impress of the light; it developed with pyrogallic into a transparent circle. It is not usual, I believe, to see the image before development, on an iodide of silver film. W. B. B.

[The plan proposed might tend to increase sensitiveness, but it would at the same time injure the keeping qualities.—ED.]

Miscellaneous.

THE DUC DE LUYNES PRIZE.—We have been favoured by Herr Pretsch with a copy of a letter received from the committee appointed by the French Photographic Society to award the prize of 8,000 francs offered by the Duc de Luynes for the best process of photolithography or photogenic engraving. The committee having examined the works of the various competitors, name the processes of Messrs. Poitevin, Pretsch, and Charles Negre as especially worthy of praise. They then proceed to state that these works give the hope of a satisfactory solution; but, considering that the results obtained as yet are not complete enough, considering, moreover, that the authors themselves have not had the time to test properly the application of their processes, nor to give them all the perfection of which they were susceptible—the commission decided that they ought not to determine the question just at present, and that the competition should be put off to April, 1864.

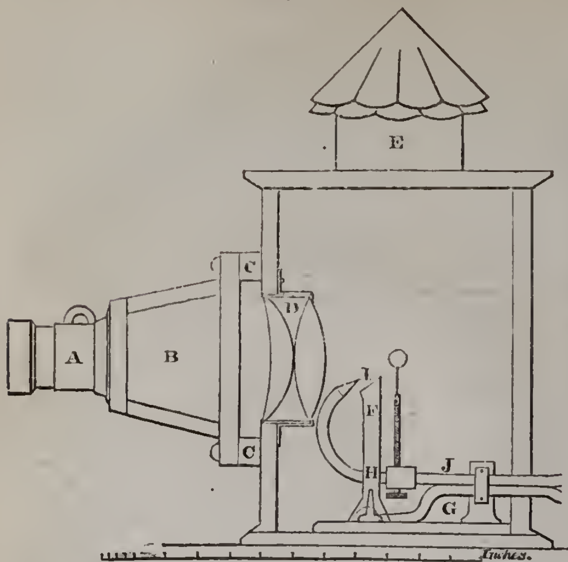
MAGIC LANTERNS.

WE select the following from the letters we have received from various correspondents relative to the use of portrait lenses with magic lanterns. Numerous readers who have made inquiries on this subject will here meet with information to guide them in their experiments.

DEAR SIR,—According to promise, I enclose you a sketch of a magic lantern, I have constructed, using my portrait lens as the objective. It is drawn to the scale of 2 inches to the foot or one sixth the actual size.

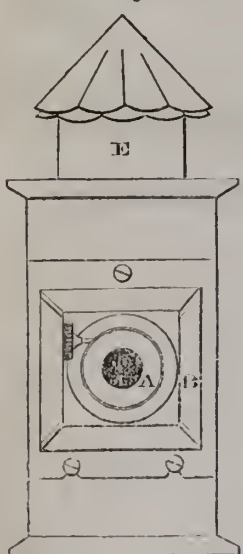
The body of the lantern is made of half-inch pine board, also the projecting front B, carrying the lens A. this part is attached to the cross-pieces C, C, by means of three screws as shown in fig. 2.

Fig. 1.



The condenser D, consists of a concavo-convex and a double convex lens, about 4 inches diameter, mounted in a tin-plate tube, and placed as near together as possible without touching.

Fig. 2.



The chimney E is also of tin with two conical caps to shut off all light.

The form of light I have adopted is a modification of the oxycalcium, the difference being in the substitution of common coal gas for the moro expensivo spirit flame. F is a metal tube, five-eighths of an inch in diameter, slightly flattened at the upper end; and the lower being sawn into threo for about an inch of its length, and bent asunder, will form a tripod or stand.

The tube G is of lead, into the end of which, at right angles, is inserted a small jet, H, with an orifice about tho size of a common pin. The gas issuing from this mixes with atmospheric air coming from below, and burns at I with a clear blue flame, free from smoke.

J is another lead, or other metal tube, conveying oxygen from the gas-bag to tho lime ball in the usual manner.—I am, sir, yours truly,

J. W. Reffitt.

Sir,—In reply to "A Reader," respecting magic lanterns, I have made one of wood of the following dimensions outside. Height 18 inches, length 12 inches, width 10 inches. The bottom for the admission of air, is on the plan of the ordinary magic lanterns. I procured from an optician two plano-convex lenses, 4 inches diameter and 6 inches focus each. These I fixed in a cell, with their convex sides facing each other. These form my condensers, which I place just within the lantern, opposite a hole cut out of the front of the lantern, sufficiently high from the bottom to be opposite the centre of the lamp. To the front of this I attached a tube of wood 10 inches long, each of the sides being $5\frac{1}{2}$ inches outside, tapering a littlo towards the end. At tho end I fixed my half-plate portrait combination (not having a quarter-plate one). The lamp is a patent moderator, for burning oil. I get one pint of pale rape oil in which I dissolve three pennyworth of camphor, which I find greatly enhances its illuminating properties. I have tried sperm oil with camphor, which is much dearer, but without any appreciable difference in the light. The light thus obtained is brilliantly white, and of intense heat. Care must be taken to have the lamp perfectly under the chimney of the lantern, which should be high and bent at the top. My chimney is made of tin. The pictures I get on the screen from the ordinary painted slides are beautiful, and perfectly sharp, but not large, owing to the long focus of the lenses.

The pictures thus produced being much smaller than I wished, I procured two more plano-convex lenses, 2 inches diameter and 6 inches focus each. These I placed each with its convex side to the lantern, just behind each other. I now get a large picture quite sharp, but the lines appear coarse, being so highly magnified. I therefore prefer the beauty of the pictures produced by the portrait lenses. I have tried photographs in this lantern, but not to my satisfaction. Being far from perfect in producing photographs for this purpose, I am looking forward with great anxiety for your promised articles on transparencies.—Yours, J. R.

Liverpool, Jan. 21st, 1861.

Another correspondent writes:—

A reader ask for information about a magic lanterns. I have made one, which is simply an oblong tin box, 13 inches long, 12 deep, and $7\frac{1}{2}$ wide, with a sloping top. I got a pair of condensers 4 in diameter, 8 inch focus, which I mounted in tin rims, which fit each other like the lid of a canister, (with tho convex sides insides); these fit in another tin rim soldered inside the lantern round the opening in front, which opening, of course, is the diameter of the condensers.

To attach my lens to the front of tho nozzle of the lantern I have a tin plate soldered on the front, with the edges beaten over, so as to form a rabbet, into which I slide the front of my camera which carries the lens, so that I can change it from camera to latern very rapidly.

I use a solar oil lamp, and have been trying to apply oxygen to it, but have not been very successful.

Proceedings of Societies.

North London Photographic Association.

The usual monthly meeting was held at Myddleton Hall on the evening of Tuesday the 30th ult. Mr. George Shadbolt in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. Woodward of Nottingham, and Mrs. Chapman were elected members of the society.

The Chairman called the attention of the members to some exquisite specimens of photography on the table, which had been presented by Mr. Bedford to tho portfolio of tho society. He took occasiou to commend Mr. Bedford's example in presenting these pictures to the members generally. The portfolio he might remind them was always on the table, except when out in the hands of some member. Any gentleman wishing to borrow it at any time, could do so on application to the secretary, who, if the portfolio wero at tho time engaged, would place the applicant's name on a list for receiving it in the order of his application.

Mr. Hughes then read an interesting practical paper on "How to ascertain the amount of silver in a nitrate bath," (see p. 51) which was received at its conclusion with hearty applause.

The Chairman remarked that on the principle that one volunteer was as good as two pressed men, he scarcely need call for a vote of thanks with applause, having already awarded it. In proposing a vote of thanks he thought they ought to include the gentleman who had assisted in and verified Mr. Hughes' experiment—Mr. Simpson. The thanks of the meeting were then unanimously voted to these gentlemen.

Mr. Hughes then stated that he had brought solutions and apparatus, and would repeat in the presence of tho meeting some of the experiments he had described in his paper.

The Chairman said whilst Mr. Hughes was preparing he would make one or two comments. In reference to the remark that for accurate experiments hydrochloric acid should be used to convert the silver into a chloride that was unquestionably true, as there was no doubt about the fact that alkaline chlorides do hold a portion of silver in the solution. Referring to the hydrometer form of instrument for testing purposes, there was an admirable instrument on this principle made by Negretti and Zambra, which being much longer in the tube, and, being used in a tall narrow vessel, afforded facilities for reading off very accurately, and experimenting with a very small quantity of solution.

Mr. Hughes said, probably if the instrument were more used still better forms might be devised. The one he had used, and which was generally prepared for this purpose, had the advantage of not taking up much space, and not requiring any other especially prepared glass to use it with, any ordinary glass answering the purpose.

Mr. Hill asked if the accumulation of other matter in old sensitizing baths would not add to the density of the solution and thus interfere with the value of the registrations of the hydrometer which were based on specific gravity simply.

The Chairman thought the experiments gave a sufficient answer to that. Here was a solution which had been in use for several years which gave results by the hydrometer test, which varied very little from those which were tested chemically, by converting the silver into a chloride.

Mr. Hughes then proceeded to test, by the several instruments named, a new 30-grain solution of nitrate of silver. The registrations were as follows :—Hydrometer gave 30 grains; Wood's Argentometer gave 32½ grains; Horne and Thornethwaites Bath Tester gave 27½ grains; and Hockin's Argentometer gave 48 grains. In course of conducting the experiments Mr. Hughes availed himself of the aid afforded by a drop of a solution of bichromate of potash, added to the silver solution, and explained the beautiful delicacy it added to the testing operation. On being added to the nitrate of silver solution, silver, having a greater affinity for chromic acid than for nitric acid, was at once thrown down as a red precipitate of chromate of silver. The silver, having, however, a still greater affinity for chlorine, left the chromic acid on the addition of the standard solution of chloride of sodium, and the red precipitate of chromate of silver gradually disappeared, until the whole of the silver was converted into a chloride, when it immediately became quite white. The colour materially assisted the eye in detecting the moment of change, and enabled great nicety to be used. The presence of the chromic acid, moreover, materially aided in causing the precipitation to aggregate, and keep the supernatant liquid clear for observation.

Messrs. Horne and Co. recommend in their published directions for using their bath tester, to add one drop of a 20-grain solution of bichromate of potash, before the addition of the standard solution, and also point out the exceptional cases where it is not useful.

Mr. Hughes then explained that the discrepancy in the results now presented doubtless was due, not to the instruments, but the manipulation, there being great difficulty in reading off with accuracy the gradations on the glass tubesby the light the distant gas afforded, and in the case of Mr. Hockin's instrument especially, more care was necessary than the circumstances afforded, the form of the instrument causing a danger of losing some drops of solution, the concentration of which made every drop lost cause a serious amount of error. In the experiments Mr. Simpson and himself had conducted, the utmost possible care had been used, and the results had been more exact.

Mr. Burr asked if any pains had been taken to test any of the solutions, and ascertain first the exact amount of silver contained, so as to ascertain the accuracy of the test afforded by the different instruments, and referred to the experiments of Gay Lussac undertaken for the French Mint, as showing an admirable method of accurate argentometry. He also asked if the methods proposed by the makers of the different instruments had been examined for strict chemical accuracy, and to ascertain whether they were based on a recognition of the same equivalents.

Mr. Hughes explained that his object had not been so much to enter into chemical refinements into which photographers generally would not have followed him. Nor had his object been to test and report upon the accuracy of the various instruments made for testing silver solutions. His aim had been to take things as he found them in the photographer's hands, and try them under the ordinary conditions which photographers would try them. He used, therefore ordinary commercial nitrate of silver, and ordinary graduated measures for measuring the solutions. The accuracy of the instruments might be gleaned rather from a comparison of their relative registrations, than by a comparison with something which he might have called a standard.

Mr. G. Wharton Simpson added that the first experiment with which he had assisted Mr. Hughes was one based on the very principle to which Mr. Burr referred, that adopted by Gay Lussac in his experiments for the French mint, and which had been introduced to photographers by Mr. Heisch.

Mr. Hughes remarked that the very delicacy of such experiments only made the danger of error greater if the measures, weights, or manipulations were not all equally delicate and perfect with the test proposed. He had not, therefore, included that experiment in his statement, as he wished to deal with the question as photographers generally would have to do, with just such facilities as were commercially supplied to them.

Another experiment was now tried with old negative nitrate solution.

Mr. Hughes remarked that this solution was handed to him by a professional photographer, with a statement that it was not working well. It was supposed to contain organic matter, which produced irregular reduction in development. If this were the case, and the bath were of the normal strength, the organic matter, unless present in large quantities, would not materially affect the reduction; but if the bath were weak, then a small quantity of organic matter would become a serious disturbing agent. The first point to ascertain, therefore, would be the strength of the bath. He would try it by Wood's test as being the easiest to manipulate.

This solution, which had been made originally made 30 grains to the ounce, now registered 26 grains. Mr. Hughes remarked that when he tried it at home it registered 22½ grains; so that it might be fair to take the mean amount, and call it 24½ grains.

Mr. Louch asked if Mr. Hughes had not in the course of his paper stated, that the collodion bath did not need testing. He thought this experiment showed its importance.

Mr. Hughes had said just the contrary, if not in so many words, at least by implication. One of the experiments recorded was with such a bath, which would not give dense negatives, and was supposed to be influenced by the cold weather. It registered by the hydrometer 16 grains, and by the argentometer 25 grains, when it had been supposed to contain 30 grains. He regarded it as of the utmost importance; and as the hydrometer was not a safe guide in such cases, he had recommended the possession of both an argentometer and a hydrometer—the former for occasional, the latter for daily use, as even a boy could use it.

Mr. Barber asked if twenty grains of chloride of sodium were added to a thirty grain silver bath, what guidance the hydrometer would furnish as to the amount of silver. He thought that the accumulation of chloride in the printing solution made this an important point.

Mr. Hughes thought this really would not occur in practice. The experiments with old baths had indicated the contrary.

Mr. Louch suggested that the argentometer could be used for the purpose of testing the purity of the silver, as there was reason to believe it was often adulterated.

The Chairman remarked that before applying it to decide such a question, the argentometer itself ought to be tested by some known accurate standard.

Mr. Hughes doubted whether it would be fair in practice to adopt the method Mr. Louch had suggested. Reversing the position, would any gentleman present, if he were the dealer, like to be judged by such a standard? The possibility of error in the graduation of the argentometer, or of the measure, or of the standard solution, or of the manipulation, would certainly render it unsafe and unfair to pronounce a sample of silver impure, or base a charge of fraud by such a standard. The experiments performed by Mr. Simpson and himself were performed with all the care of which the appliances would admit, and yet they had some variation in result, on performing the experiments twice.

Mr. Quin remarked that there was a very simple and elegant test for the presence of adulteration in nitrate of silver. If the whole of the silver in a nitrate solution were thrown down by means of pure hydrochloric acid, and a drop of the supernatant liquid evaporated on a glass, there would be no crystalline residue if the silver were pure. If on the other hand nitrate of potash or nitrate of soda—the commonly supposed adulterating salts—were present they would crystallize on evaporation.

The chloride of silver might be further tested by dissolving in ammonia. He had not, however, on any occasion found any wilful adulteration present in commercial samples; although they were frequently much contaminated with organic matter.

Mr. Dawson, referring to the printing bath, thought that the accumulation of the nitrates of potash, soda, or ammonia would affect the specific gravity.

Mr. Hughes again referred to the evidence of the experiments. Mr. Simpson and himself first took a new solution and tried the hydrometer and the argentometer, and found that they agreed within one or two grains; they then took old solutions and found that the discrepancy was no greater. He had scarcely been prepared for so little disturbance of the specific gravity; but there were the facts. He thought that perhaps the fact was overlooked that comparatively little of soda, potash, or ammonia was dissolved into the bath; but was chiefly retained by the paper. If these salts had been largely present they would undoubtedly have had a more disturbing effect. A thirty grain solution of nitrate of soda would register with the hydrometer only twenty grains.

Mr. Simpson suggested that as the albumen was coagulated immediately on contact with the nitrate of soda, that would tend to imprison the soda, potash, or ammonia, and prevent its rapidly dissolving into the nitrate bath.

A general conversation on this subject ensued, in which Mr. Hughes explained that the experiments had in each case been tried with a drachm of nitrate solution, but had been stated in ounces; of course by this method any fraction of error was multiplied by eight.

Mr. Dawson remarked, that the hydrometer principle was so simple that he had prepared several graduated for different strengths; and, in mixing new solutions, used them instead of weighing out the silver: but for old solutions he had not the same confidence in using them.

Mr. Hill referred to silver baths, in which almost the whole of the albumen was dissolved off the paper, as affecting specific gravity.

Mr. Dawson said an impression prevailed, that it was the weakness of the silver bath which caused the albumen to be dissolved. He thought that this was not always the case. He had tried albumenized paper on new baths of all strengths, down to five grains, without dissolving the albumen. He thought it was rather due to the accumulation of ammonia in the bath, or even in the paper; the compounds of ammonia being so unstable, he thought that it sometimes existed free in the albumenized paper.

After some further conversation the subject dropped.

The Chairman then called attention to the election of officers which would take place at the next meeting, any member being at liberty to nominate such gentlemen as he thought suitable.

Mr. Hill announced that Mr. Barber had just promised a paper on "The Purification of Nitrate of Silver," for the next meeting. The subject would form a fitting sequel to Mr. Hughes's paper.

The proceedings then terminated.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 30th January, 1861.

Our photographic atmosphere has been intensely agitated by the tidings that the problem of photographing on wood is successfully solved. Our expectations have been frequently raised to a high pitch, and as frequently disappointed, but as there appears to be no doubt about the fact on this occasion, we may venture to shout and clap our hands in consonance with the ingenious discoverer's "*Eureka!*"

As it is known to a select few in this metropolis that I am the individual honoured in the appointment of being your "Special Correspondent," of course I was besieged with applications for specimens of photography on wood. These I regret to say I could not gratify in the manner I desired; but a copy of the *Illustrated London News*, containing a representation of one of Flaxman's bas-reliefs stood me in good stead. I hope, however, to obtain some wood blocks with designs photographed upon them, in time to exhibit at the next meeting of our Photographic Society; in that case I will report to you the opinions which may be expressed on this, one of the most important applications of photography yet made. It will doubtless effect a great change in the art of wood engraving, a change for the better too, as the photographed designs will demand more artistic capability on the part of the engraver than designs drawn in the present manner on the wood obtain.

In analysing the effects of the action of the atmosphere upon milk, it is found that it absorbs oxygen and gives off carbonic acid, the volume of the latter gas being much greater than that of the oxygen absorbed; this exchange takes place very rapidly after the first four-and-twenty hours, so that milk in contact with a volume of air greater than it own bulk absorbs all the oxygen in the course of three or four days. M. Stoppe concludes that there is formed at the same time compounds richer in carbon and in hydrogen. To determine their nature, he took two portions of the same milk; the one was mixed with alcohol and analysed immediately; the other was not analysed until several days afterwards; the result of these experiments, many times repeated, was:—1st, that the milk exposed to the air left considerably less solid residue than the same milk fresh; 2nd, that the milk that was exposed to the action of the air was comparatively richer in fatty matters than the milk to which alcohol was added, and immediately analysed.

Dr. Ozanam has published the conclusions derived from his researches upon the action of chemical agents upon the false membrane that appears in croup and diptheria. He studied, in succession, the action of pure water, of bromine, chlorine, iodine, bromide of chlorine, chloride of iodine, sulphuric, phosphoric, hydrochloric, hydrofluoric, and citric acids, the juice of lemons, potassa, soda, ammonia, baryta, lime-water, chlorate of potassa, perchloride of iron, bichloride of mercury, &c. Those that are really efficacious, divide themselves, according to their action, into two classes, solvents and alterants. The principal solvents are:—the *mother waters of soda*, which effects a complete solution in two hours; *soda* softens the membrane in a quarter of an hour; *bicarbonate of soda* effects a complete solution in twelve hours; *urea*, a perfect solution, leaving no traces in twelve hours; *cyanide of potassium*, complete diffusion in fifteen hours; *glycerine* softens almost to complete solution after four-and-twenty hours; *lime-water*, softens and breaks up the membrane after twelve hours, and effects complete solution in twenty-four hours; *bromide of potassium*, complete solution after twelve hours; *subcarbonate of potassa* softens and renders transparent after twelve hours; *phosphate of soda* softens considerably in twelve hours, and effects a solution in three days; *chlorate of potassa* effects solution after three or four days.

The principal alterants are *iodine* which hardens the membrane like a piece of leather, in an hour; *perchloride of iron* hardens it in twelve hours; *bichloride of mercury* hardens it very rapidly; *chlorate of potassa* slightly hardens it. Mr. Ozanam has forgotten to try Peligot's solvent for vegetable cellulose, the cupro-ammoniacal liquor. From these researches it will be seen that the most efficacious agents are those which nature has supplied the most abundantly:—sea-water, carbonate of soda, and, lastly, glycerine.

A new preparation, to which the name *heveone* is given, to indicate that it is obtained from caoutchouc, extracted from the *Hevæa guyaniensis*, and prepared under very high temperature, is proposed by M. Mathieu, a surgical instrument maker, as a vegetable *grease* for lubrication and other purposes. This substance possesses some very remarkable properties, and will render great service to numerous branches of industry. It strongly adheres to the surface of the substances to which it is applied; it never becomes oxydised under the influence of atmospheric agency; it renders unoxydizable, and preserves from rust articles of iron, steel, and copper, or in fact any polished metal, when they are covered with the thinnest possible film of *hevone*. Surgical instruments, domestic utensils, machines, arms, weapons, tools, can be kept always bright and clean. The lubricating properties of *heveone* are still more remarkable; applied to pistons, axles, hinges, screws, or other things submitted to friction, it renders their action much smoother, and it never loses its viscidity nor becomes dry, nor oxydizes, nor combines with the metals to clog the bearings. Heveone being impermeable to water, powerfully contributes to preserve intact and clean objects manufactured in leather, as boots, and shoes, harness, pulley-bands, &c., it protects them from the extremes of humidity and dryness, making them very supple and preventing decay. Its salutary effects extend also to wood exposed to the weather, as in gun-carriages, &c. Lastly, a very valuable quality for firearms, that of rendering them much easier to clean, and also to require cleaning less frequently.

The spontaneous change forged and rolled iron undergoes when submitted to continuous vibration, is productive of such critical danger, especially in the case of railway machinery, that an investigation into the best means of remedying the resulting evils, has been viewed as an engineering question of vital importance. Among others, Mr. Schimmelbuch, of Liege, has undertaken the subject, and the following is an epitome of his investigations. A bar of pure unalloyed iron was struck by a hammer three times in a minute for six consecutive weeks, at the expiration of this time it broke into three pieces. Before the experiment the bar was a good specimen of fibrous iron; after, on the contrary, its fracture exhibited a brilliant crystallized structure, resembling that of antimony.

A bar of iron alloyed with nickel, submitted to the same treatment, underwent no change.

A very simple means exists of recognising this changed condition of iron, so dangerous in its consequences. Pure iron, when magnetized by contact, loses its magnetic properties immediately the needle is detached. On the other hand, iron combined with minute quantities of some foreign body, such as carbon, oxygen, sulphur, or phosphorus, remains magnetised. The efficacy of this simple test has been established by repeated experiments.

Specimens of iron alloyed with carbon, manganese, zinc, cobalt, tin, chrome and nickel successively tested, show that nickel is the only one that can be adopted commercially to correct the tendency to crystallize in pure iron, which it is so desirable to overcome. The quantity of nickel required to produce the desired effect varies between 1 per cent. and the $\frac{2}{1000}$th part.

Mr. Schimmelbuch's experiments were directed chiefly to studying the effects of the addition of the mineral *wolfram* to pure iron. This addition imparts the greatest hardness tenacity, and density to the iron; invaluable qualities in axles of machinery, locomotives, steam-boats, and in steam-cylinders, light cannon, &c. The most inferior kinds of iron acquire an extraordinary tenacity, and a hardness superior to that of cast steel, by the addition of 2 to 5 per cent. of this mineral, according to the quality of iron employed.

Phosphoric or sulphuric iron become very tough and strong by the addition of $\frac{1}{2}$ to 1 per cent. of wolfram, and 3 to 5 per cent. renders it extremely hard. Iron thus treated does not lose these qualities even after a second or third fusion, and the castings are free from bubbles.

The addition of wolfram to copper and its alloys exercises the same beneficial action. The addition of one-half per cent. imparts great tenacity; whilst 2 to 4 per cent. renders the copper very hard, without in the least diminishing its tenacity.

The most important consequences to engineering science will doubtless result from these and other investigation, conducted with the same object.

M. Pisani has communicated to the *Academie des Sciences* a new paper on certain reactions of the salts of iron, uranium and alumina, and on the separation of uranium from iron. Hitherto we have almost exclusively attributed to the non-volatile organic acids, such as tartaric acid, the privilege of preventing certain reactions by their presence: but it has been recently observed that oxalic acid, in certain cases, acts in the same manner: for, as was stated in our last, its presence prevents the blue precipitation of the salts of iron by yellow prussiate of potassa. The following are some analogous facts observed.

Salts of Iron.—If oxalate of ammonia be added in excess to a salt of iron at its maximum neutrality, then acetic acid be added, the solution retains its yellow colour, and does not redden, as usually happens, in consequence of the formation of acetate of iron. In this same solution phosphate of soda does not precipitate phosphate of iron, but ammonia and sulphide of ammonium separate the whole of the iron, as usual. If, instead of acetic acid, we employ acetate of soda, the liquor no longer becomes coloured, but then it precipitates by phosphate of soda. To produce these reactions, as much oxalate of ammonia must be added to the solution of the salt of iron for its yellow hue to change to greenish yellow.

Salts of Alumina.—Alumina, in presence of a great excess of oxalate of ammonia, is not immediately precipitated by ammonia and sulphide of ammonium; but in a short time, according to its proportion, it is precipitated, especially with the aid of heat. We can also, with phosphated alumina, recognise phosphoric acid in this solution by a salt of magnesia; but this method cannot be recommended, for it is probable that it is precipitated as soon as the alumina. Thus oxalic acid plays only but for a short time the part of tartaric acid with the salts of alumina.

Salts of Uranium.—Nitrate of ammonia, in presence of oxalate of ammonia, is not precipitated red by yellow prussiate of potassa. It is precipitated by phosphate of soda in an acetic liquor; but if oxalate of ammonia be previously added to this solution, the phosphate of soda gives no precipitate as in the case of the iron. If ammonia be added, all the uranium is precipitated in the state of phosphate; but if phosphate of soda be not added, the precipitation of the uranium by the ammonia will be incomplete, and to precipitate the remainder phosphate of soda must be added.

Separation of Uranium from Iron.—When carbonate of ammonia is employed, as usual, to effect this separation, it always dissolves a little sesquioxide of iron with the uranium. Yet there is a way of perfectly effecting this separation—as the oxalate of uranium in solution in the carbonate of ammonia is not precipitated by sulphide of ammonium, it is only necessary to add to the liquor separated by filtration with the oxide of iron, some drops of this latter re-agent to eliminate the little iron that has been dissolved in the state of sulphide. After another filtration we have a liquor containing all the uranium without any traces of iron.

The preservation of organic alimentary substances is a matter of great importance, and numerous ingenious processes have been suggested from Appert down to Chollet, which accomplish the desired object more or less effectually, by means of excluding the air, dessication, &c., at the same time it is felt that there is a degree of complication in all these processes which creates great expense, and militates against their general adoption. A new process consists in causing the surface of the material to be preserved to imbibe and become thoroughly penetrated by a substance which possesses the advantage of being itself alimentary, and of having an agreeable taste, which can be taken in considerable quantity without causing any derangement of the stomach, similar to that caused by salted provisions, while at the same time it possesses the advantage of being very abundant and cheap. This substance is sugar, or rather a residue of its manufacture, viz., molasses. It is employed in the following manner:—The meat to be preserved is cut into slices, or portions of moderate size, and immersed in molasses of ordinary density, such as is delivered at the sugar-bakers; that sold retail is frequently adulterated, or weakened by the addition of water. By the natural phenomena of endosmosis and exosmosis, a balance is soon established between the greater density of the molasses and the weaker liquids contained in the meat, so that in the course of time the molasses acquires a certain degree of limpidity, which is a sure index of the meat having become completely penetrated by it, which is effected with more or less rapidity according to the thickness of the pieces. When the operation is completed, the meat is withdrawn from the molasses and washed in plenty of water, suspended in a current of air, and left to dry spontaneously. Meat prepared in this manner can be packed in boxes and casks, and sent to any distance without undergoing any deterioration.

It has been observed that chloride of lime kept in a bottle for some time undisturbed, is liable to spontaneous detonation: this phenomenon is explained thus:—The chloride of lime being always moist, decomposes water, especially under the influence of the solar rays, and liberates oxygen. This decomposition proceeds very slowly, until the moment arrives when the excess of oxygen breaks the bottle with violence. To avoid this accident is is only necessary to open the bottle occasionally.

An interesting reaction takes place when pure dry hydrogen and the vapour of perchloride of phosphorus ($Ph\,Cl^5$) are passed together through a glass tube heated to redness. Under these circumstances we observe the formation of hydrochloric acid gas, and liquid protochloride of phosphorus ($Ph\,Cl^3$). At the same time a certain quantity of phosphorus is set at liberty, disengaging a gas which burns with an emerald green flame, and producing white fumes of phosphoric acid. This is a mixture of gaseous phosphoretted hydrogen and excess of free hydrogen. Oxygen, at the temperature of a dull red heat, also acts upon the vapours of perchloride of phosphorus. The reaction is accompanied by a vivid light. In this case there is a considerable disengagement of chlorine: the tube retains the woolly flocks of anhydrous phosphoric acid, which gradually attack the glass in the parts heated to redness. In the cold receiver a liquid is condensed which is coloured yellow by the chlorine it holds in solution. This liquid, distilled after being agitated with mercury, becomes colourless, it is oxychloride of phosphorus. ($Ph\,Cl^3\,O^2$).

This, in M. Baudrimont's opinion, is the first instance of the direct substitution of free oxygen for combined chlorine. Perchloride of phosphorus also gives rise to a reaction when put in contact with chlorate of potassa. When three equivalents of the perchloride are mixed with one equivalent of the chlorate, both in a state of powder, a liquified mass is obtained, the temperature rises, hypochlorous gas, then chlorine, are disengaged. The residue of the reaction is chloride of potassium in supension in oxychloride of phosphorus. No reactions like the above-mentioned take place when nitrogen is operated with.

PHOTOGRAPHY IN GERMANY.

Elberfeld, Jan. 23rd, 1861.

Mr. Hardwich's opinions. expressed in the "Photographic Comments, No. XVI." of your Liverpool contemporary, differ in some points from those of many photographers. The alcoholic collodion has without doubt a decided advantage over the ethereal, provided it be composed of pure chemicals and in the right proportions; then it is stable with every iodide.

The iodide of lithium has received an unfavourable judgement in the said "Comments," and why? Because it has reddened the author's collodion. But is this a determinating proof? Do not the iodides of ammonium, potassium, or sodium do the same? Prepared in the manner which has been indicated by Dr. Schnauss, and by ourselves, the lithium-collodion is as stable as any other collodion. There have been many hundreds of pounds of this preparation made after our own formula, which have been pronounced to possess all the favourable properties we have claimed for this collodion. It remains of a light yellow colour at least one year, perhaps yet longer; even sent to hot countries it does not change its colour; besides, it is more sensitive than any other collodion. The conditions under which a good collodion possessing any properties we like to give it, are very easily stated. Three mean points must be regarded:—

1st. The plain collodion must contain an excess of alcohol, and the pyroxyline must be prepared in strong acids at a high temperature; the collodion must contain a sufficient quantity of pyroxyline so that we are able to add enough iodide to produce a dense film.

2nd. All preparations must be perfectly pure; if not, every success is put into jeopardy.

3rd. Every iodide has the property either to redden colourless collodion, or to decolourise reddened collodion. There seems to be no iodide without effect upon one or the other, red or the colourless collodion. Most of the proposed iodides redden colourless collodion; they stand in the following order: The iodides of iron, lithium, ammonium, magnesium, potassium, sodium, zinc. On the other side, only the iodide of cadmium stands, all the bromides following in the same direction. The first-named combinations therefore have in a more or less high degree the effect of acids; the latter that of an alkali. It is a curious fact that the iodides resembling in their effects to an acid, nearly all have an alkaline reaction; the iodide of cadmium has, on the other hand, an acid reaction.

Collodion iodized by a single iodide of the first series may give good results, but never will do so for a long time; it will soon become discoloured and lose its valuable properties, *i.e.*, it will get insensitive and give hard pictures. Some persons make use of this circumstance in employing an old collodion for the reproduction of objects which permit a long exposure, as prints, drawings, &c., also for views and landscapes. Nothing can be said against this application, because by a red collodion the lights are rendered more dense in the negatives, and the shadows more transparent. But for portraiture this kind of collodion dare not be used, because it is not sensitive enough, but principally because it gives too dense lights and no half-tones. Cadmium-collodion, prepared with good and neutral plain collodion, gives opposite results, *i.e.*, weak pictures; and only after a certain time obtains the property of giving a sufficient intensity.

To make a collodion which works well soon after its preparation, and retains all the good qualities (which may be given to it by the composition and proportion of the different substances) some years without alteration, we need the mixture of some iodide of the first order with iodide of cadmium: the first one in a small excess. When using the sodium iodizer we need the addition of less iodide of cadmium, than when using the ammonium iodizer. In approximate proportions iodide of lithium demands the half, iodide of ammonium or potassium the third part, iodide of sodium the quarter of its weight of iodide of cadmium.

Sodium-collodion has now come more into use. I can recommend the following formula as being very excellent:—

Ether ·725	200 parts.
Alcohol ·815	400 „
Pyroxyline	7 „
Iodide of sodium	8 „
Iodide of cadmium	2 „
Bromide of cadmium	2 „

The pure iodide of cadmium is a very stable salt in white crystals; the powdered yellow substance commonly sold under this name should never be used.

In my last letter I spoke of a second acetate of silver bath to be used after the nitrate bath for collodion pictures; some persons have tried it and found that it possessed all the advantages claimed for it; it allows shortening the time of exposure, and produces fine transparent negatives, which may be copied in half the usual time—two properties of value in these days of twilight. Should the negative seem too transparent after fixing, a little more vigour may be given to it by a diluted solution of chloride of gold.

The acetate of silver is prepared by mixing hot concentrated solutions of acetate of soda and nitrate of silver; during the cooling the new combination crystallizes out of the fluid.

The rage for *cartes des visite* is growing over the whole of Europe, also in Germany this beautiful style of pictures is much liked. At Vienna, M. Louis Angerer, the photographer of the Emperor of Austria, has the most fame, his beautiful arrangements, consisting of the richest sculpture and finely painted backgrounds, are much praised. Messrs. Haase and Co., of Berlin, sell incredible quantities of the carte-portraits of King William I., and the Royal Family of Prussia. The *Kladderadatsch* remarks:—"About this time rages at Berlin the portrait-visite-cartomania, during which the photographers of this town generally know how to occupy themselves more profitably than the honourable public. The sun, whose powers are tasked to the utmost at this opportunity, like other ill paid *ouvriers*, determines to go gratulating her customers upon new year." A wood-cut shows the sun knocking at a photographer's door; in the left hand she holds a box with the inscription, "for cleaning the solar spots!"

Professor Ludwig, of Jena, a distinguished chemist, has stated the recent analysis of "Encre photographique." It consists only of nitrate of silver and potash. In the last number of *La Lumière*, M. Gaudin hopes the analysis has not been executed upon the right "encre;" but I can certify this, because I myself bought the analysed sample of the known "Société."

The "Association of German Photographers" is always increasing, so that two new districts have been founded this month at Augsburg, and at Flensburg, in Sleswick. Under the recently joined members are Mr. Radl, one of the first German photographers of Augsburg, Count du Ponteil, a dilletant of Munich, John Sholto Douglas, Esq., of Thüringen, and Mr. Maar, Director of the Albrecht-Dürer-Association, of Nürnberg. A special periodical only for the members of this society appears now under the title of the photographic salutation, "Good Light!"

PAUL E. LIESEGANG.

COAGULATED ALBUMEN.

DEAR SIR,—If Mr. Sebastian Davis will attentively reread my letter, he will find that it has no relation whatever to the temperature at which albumen will coagulate; I simply mentioned 165°, as it would not admit of cavil, but still being 15° *below* the temperature to which he had submitted his plate. In his reply (which is *no answer* to my letter) Mr. Davis says:—"In my experiment the albumenized plate was heated and dried simultaneously at 180°, so that both the structural and chemical properties of the film *must have been altered by the process of coagulation.*"

Will Mr. Davis allow me to say, that the words I have put in italics are only *assumption*, as he proceeds to say,—"that the thin layer of albumen resting upon a collodion film can thus be entirely converted into its insoluble state, *may fairly be questioned;*" but even giving him the benefit of his own belief, that it is "*partially coagulated*," was he warranted in saying that his experiment seemed to contradict Dr. Riley's theory? Mr. Davis's albumenized plate was either coagulated or not; if *not*, it had nothing to do with Dr. Riley's experiment; and if it be questionable whether it was not a *mixture* of coagulated and dried albumen, it had still nothing to do with the question, as Dr. Riley's was *wholly coagulated.*

The erroneous notion, to which I sought to draw your attention, was the supposition that *heating and drying* the plate *coagulated the albumen.* I sincerely trust that Mr. Davis will not suppose my remarks had any *personality* in them. The question, whether the film of albumen can be coagulated by *drying the plate* at any temperature, however high, is of too much importance to be passed over slightingly; and I am very sure it cannot be left in more able hands than Mr. Davis's, if he will but experiment upon the subject without any bias.—I remain, dear sir, your sincere well-wisher, G. P.

SIR,—Mr. Davis, in your last number, has strangely misunderstood the letter of "G. P." in your journal of the 18th ult. "G. P." does not raise the question as to the degree of heat necessary to coagulate albumen, but whether drying an albumenized plate does not simply dry the albumen instead of coagulating it. The opinion that it is coagulated by dry heat is the erroneous idea which he draws your attention to.—Yours, &c. FAIRPLAY.

Lewisham Road, January 28th.

THE LONDON PHOTOGRAPHIC SOCIETY.

PROGRESS *versus* CHANGE.

SIR,—While entirely coinciding with the views expressed by "Progress," I think we cannot be too careful that our society does not degenerate into the gossiping-club style, of which we obtain a glimpse in the letter elicited from "A Former Member." What with "gossip and chat" they doubtless are, as he says, very "merry and happy," and it would seem they only need add "pipes and baccy" to complete their felicity.

No doubt our machinery is too heavy and stately, and not elastic enough for these latter days, but we cannot afford to throw overboard names which give weight to the society. Also a due amount of "ballast" gives security, and though without it we might attain to a greater speed, we should jolt considerably more. Above all, beware of the danger of *changing King Log for King Stork.*

I think with "Progress" that there should be a kind of "upper house," to which all those who have done good service, and who cannot be expected to devote their time to the details of business, should be promoted: and that a practical, energetic executive should carry on the government. The functions of secretary and editor should be divided, and the editorship of the *Journal* of the society put into more active and spirited hands. There should also be an inner circle of members, beariug some title as distinctive as the R.A.'s of the Royal Academy. The number should be very limited, and none eligible for election who had not distinguished themselves in some way—either in the practice or theory of the art—and who might thus write F.P.S. after their name, with as much laudable pride as an F.R.S. Funds—those sinews of war—would not be wanting if the society was really felt to be a fostering *Alma Mater.* I do not believe, if the subscription were doubled it would be begrudged, if it really fostered talent and the money was well spent. The annual subscription to the Geological and other societies is £3 3s. The Photographic Society should not be poorly cramped in that particular. It should possess real power—power to act, power to complete and carry out what individuals cannot, remembering that union is strength. It should be the arena into which every aspirant might throw himself with confidence; but, as at present constituted, let him beware of the cold shade of the society.

Hitherto, the photographer's has been such an anomalous position, too often a by-word synonymous with charlatan, quack, &c., that men have been fain to drop the appellation in private circles; but the time has come when they ought to remember the old aphorism, "respect yourselves, and others will respect you."

Let the society assert itself—let its members raise their standard, intellectually and practically, and they will draw a broader line of demarcation than can be done by any petty exclusiveness. Let there be some better system organised respecting the reading of papers before the society, to insure that the papers themselves are not the tedious "twice-told tales" we are too often called upon to endure. Let it be remembered that it is a place for the advancement of the art, rather than of the individual—though the latter will come as a concomitant, if not sought as an end. Let them remember it is not a place fer the flippant discussion of trade merits—not a place to puff their wares; and the society may one day rank with any other of the learned societies.

REAL PROGRESS.

Talk in the Studio.

Artistic Photography.—Our talented contributor, Mr. A. H. Wall, who for some years past has been a partner in the photographic firm of Cotton and Wall, in the City, has just dissolved connection with his late partner, and is about opening an establishment for the prosecution of artistic photography, and colouring for amateurs and the profession, in Old Bond-street.

Architectural Photographic Association.—An interesting lecture was delivered on Tuesday evening by E. J'Anson, Esq., on the "Photographs of French Renaissance Architecture." The lecture was more essentially on the Renaissance Architecture than on the photographs, which were used to illustrate the subject. In some cases where photographic specimens were wanting, drawings were substituted. In the majority of these cases, notwithstanding that the drawings possessed considerable merit, the superiority of photographs for architectural illustration was strikingly manifested.

Ethno-Photographic Gallery.—A gentlemen writing to the *Athenæum* points out the importance of applying photography to the preservation of Ethnographic records. He says:—"Great and interesting changes, of which no exact record is kept, are taking place in the condition of the human family in every part of the world. Some races of men are dying out before our eyes, and others becoming greatly modified by a variety of circumstances. English, Scotch, and Irish are becoming one people by intermarriages, and we are all gradually changing by the influence of civilization. Locomotion is mixing races everywhere in both the Old and New Worlds; soon a pure race will (if not already) cease to exist. The Red Indian is fading away rapidly; the Anglo-Saxon is undergoing a great modification in North America. Everywhere faces and forms, of which the ethnologist would long to preserve authentic memorials, are becoming extinct: any likenesses preserved are but rough inexact sketches. Is it not desirable, now that in photography we have means to do something to provide for ourselves, and to hand down to the future ethnologist the exact features and form of head, at least, of the leading races, sub-races, nations as they now exist? Would not an ethno-photographic portrait gallery, exhibiting the face and forehead in one view, and the profile and rest of the head in another, with a record of a few measurements, be of great value to those who desire to study the questions of race as well as of great general interest? How valuable are the exact and reliable sketches in M'Kenny's "Races of Man;" and how very interesting was the clever sketch in *Punch's* "International Race of 1851." If you think this a suggestion of any interest, I should be glad if you would bring it before your readers. It would be a formidable undertaking, but not beyond the power of rich and enterprising England.

A Photographic Banquo.—A certain small photograph, about the size of our visiting cards, of which strange tales are told, is now selling in large numbers all over Italy. It is the portrait of an Italian soldier, who having attempted the life of the king was cruelly executed. For some time previous to his downfall, it is said that this photograph, like Banquo's ghost haunted the tyrant. Mysteriously enough, and in defiance of all precautions, it is said to have met his eyes at all hours and in all places, until there seemed something supernatural and ominous in its ever recurring presence. When he knelt before the Virgin's shrine, in his morning orisons, there, about the neck of the image, hung this photograph. When he attended mass and opened his missal, there was the soldier's portrait. At dinner, when he unfolded his napkin, out fell this identical photograph, and when at night he retired to rest, within the well-guarded sanctuary of his slumbers, there, laid boldly upon the very pillow of his couch, he found this picture, this strange production of an art which he had banished from his crime and terror-haunted dominions. A Garabaldino, whom we have just welcomed back from his generous and dangerous labours in behalf of an enslaved country, showed us the portrait, and said it was thought in Italy that the king's singular flight from an enemy quite unable to compete with his well-organised and far more numerous forces, was to some extent attributable to the state of bewilderment and terror brought about by these unaccountable incidents. Be this true or not, certain it is that in consequence of the interest thus attached to the photograph in question, it is rapidly selling all over the newly liberated country. Most of the English Garabaldini have brought over one or more.

To Correspondents.

Stereoscopic Exchange Club.—A correspondent writes to say that he forwarded pictures for exchange to two members of the Exchange Club, to one on the 27th of November, and to another on the 17th of December, without yet having received any return. Where members have not a supply of specimens already printed, the recent weather may have operated as an insuperable barrier to the prompt return of exchanges. We should be sorry to think that any want of confidence in each other was arising in the minds of members. Where suitable pictures for exchange are not in hand, and the state of the weather precludes their preparation within a reasonable time, we would suggest that an intimation of the fact by post would be desirable. *Verbum sap.* Our correspondent adds, that except in the instances he names, he has been much gratified by his exchanges.

B. W. R.—We have more than once given an opinion on Dr. Hill Norris's Instantaneous Plates. So far as our experiments have gone they fully meet the conditions claimed for them; but they require great care and cleanliness in manipulation. The photographic ink we have never tried. The analysis of Dr. Schnauss, given by our German corresponpent, stated it to consist simply of an adulterated solution of nitrate of silver.

Prendergast.—The advantage of using a portrait lens in the magic lantern is in the superior definition obtained. The disadvantage of the image being generally small. See the letters in another column.

J. P.—Under-exposed pictures fog frequently in developing, because the free nitrate of silver is reduced by the iron solution before the latent image is developed. The condition of the nitrate bath, of the collodion, and of the developing solution, may all tend to bring about the same result. If the collodion be new, or the bath or developing solution deficient in acid, the tendency to fogging from under exposure is increased. A little longer exposure, more acetic acid in your developer, or the use of an older collodion are the best remedies. The addition of a little tincture of iodine, or of hydrobromic acid to your collodion will sometimes have a similar effect as age upon it.

R. C. R. B. J., India.—1. There is no remedy for your pictures being out of focus, but more careful manipulation; unless indeed, the lens or camera be at fault. The specimens you send appear tolerably sharp, but require more carefully lighting. There is too much top light, giving heavy shadows under all the features. You will get more half-tone, by the addition of a bromide to your collodion, about half a grain to the ounce. The pin holes may proceed from dust, or a turbid bath, or a very old bath, or from the collodion not being quite settled. 2. The defects you mention in your collodion positives appear to arise chiefly from the use of an unsuitable collodion. Varnishing will improve them. 3. The prints have the appearance of having seen the light either before printing or toning, or the paper may have been excited a few days. Take great care that the paper is not exposed to any white light except such as passes through the negative, and let the printing and toning succeed the sensitizing as rapidly as possible; use the alkaline gold toning process and fix in new hypo. 4. For dry plates try the collodio-albumen process. You will find formulæ for collodions and for various developing solutions repeatedly given in our pages. You will find many excellent processes collected and carefully stated in the Photographic News Almanac for this year. Mr. Cramb has not yet published his formula, but you will find a formula for the albumen process in the present number.

M. M. D.—The chloride of gold should be neutral; not so much because it will give better tones; but because there will be less danger of the toned print decomposing the hypo fixing solution. It is an excellent plan to make every 15-grain bottle of chloride of gold at once into a solution of, say 15 ounces, and keep it so for use, neutralizing it at the time. Most commercial samples will probably require from half a drachm to a drachm of carbonate of soda to neutralize it. Test with litmus paper.

Un Pauvre Homme.—Your glass specimen was smushed beyond the possibility of forming any idea of its quality. The defects to which you refer in the eyes, are probably due to your inefficient mode of lighting. For successful portraiture a properly lighted glass-room is indispensable. The next best method of lighting is in an ordinary room with a large bay window facing north, and using reflecting screens. Applying black varnish to the collodion film is a sure method of spoiling a collodion positive.

J. C.—You have added too much acetate of soda to your bath, which became surcharged with acetate of silver. The crystals reappeared because you had neutralized the nitric acid. Excess of acetate of silver has a tendency to produce fogging, especially with an iron developer. We prefer to neutralize nitric acid with oxide of silver, and avoid acetate of silver in the bath, where it can be dispensed with. 2. For the Fothergill process one of the first requisites is a suitable collodion; one containing a bromide is best. Ponting's collodion has a high reputation for the wet process, but we believe it is not very suitable for the Fothergill process. *Ackland's Hints on the Fothergill Process* contains some excellent advice. 3. To recover the silver from clippings, filter papers, &c. burn them in a crucible with equal parts of carbonate of potash and carbonate of soda. See articles on "Photographic Chemicals" at present in progress. Transparencies may be printed by the wet process in the camera, or by the dry process by superposition. The latter is the best if you are practised in a dry process. They may be toned with gold. See article on the subject shortly.

A Bungler.—The process for producing yellow negatives, recently given, is very simple. You have probably attempted it with one solution not properly prepared. First, whiten with a solution of bichloride of mercury, 20 grains to the ounce, and then wash well. Next apply a solution of iodide of potassium, three or four grains to the ounce, which will turn the whitened picture yellow. Your silver solution is spoiled by the hyposulphite of soda. You must now simply recover the silver by the process given in articles on "Photographic Chemicals," which we are at present publishing.

E. A. H.—Inhalation of the fumes of cyanide is decidedly prejudicial, and should be avoided. Hyposulphite of soda may be used for fixing positives, but cyanide generally produces a whiter tone. The operating room should always be kept as well ventilated as possible, as inhaling the fumes of many of the chemicals is unwholesome.

M. A.—A new edition of "Hardwich's Photographic Chemistry" will be ready very shortly. It will, doubtless, be advertised in our columns when out. Common washing water may be kept in an unvarnished barrel, and an ordinary brass tap may be used. Distilled water is best kept in a large stoppered bottle. We shall have pleasure in receiving a communication on the subject you name.

Insensitive and others next week.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 127.—*February* 8, 1861.

THE PHOTOGRAPHIC EXHIBITION.

Portraiture.

A noticeable circumstance in connection with the present Exhibition, is the absence of specimens from many of the best known portraitists and former exhibitors, Williams, Mayall, Kilburn, Hennah, Herbert Watkins, Silvy, and some others who enjoy a high reputation for this branch of photography, and who have on former occasions contributed to the Exhibition, more or less largely, are this year "conspicuous by their absence." The first two gentlemen, perhaps, are scarcely correctly included. Mr. Williams has sent recently, some time after the Exhibition was opened, two or three vignettes of children, which are very pretty, but scarcely up to the specimens of former years, and Mr. Mayall has contributed the series of album portraits of the Royal Family, with which the public is familiar.

One of the first reflections which occur to us after an examination of the portraiture here, is that this most universally interesting and most largely practised branch of our art, at least amongst professional photographers, has not progressed in nearly equal ratio with some other branches. The portraits generally, do not strike as better as a whole, than they were several years ago. There is not a frame now exhibited of better pictures, in every sense of the word, than Hennah exhibited half-a-dozen years since, whilst we scarcely remember to have seen any exhibition with such a prevalence of good landscapes. We scarcely know to what this may be attributable: whether portraiture attained its maximum of excellence earlier than landscape photography, or whether having attained a certain status, the commercial exigencies of the profession have maintained it at the dead level of goodness which it had attained, without attempting to take it higher, or whether the best pictures have not found their way to the Exhibition, we cannot quite pretend to say. There are certainly many excellent portraits, some few very good indeed; but we cannot help thinking that we have seen a great many better than those which form the staple at present in Pall Mall.

One consideration we cannot forbear suggesting as a possible reason why portraiture generally has not progressed in equal ratio with landscape photography. It is that many portraitists, confessedly, "have not time to read the journals," and think they know all that need be known about photography, without bothering themselves with new ideas. We are, possibly, scarcely unprejudiced in our judgment, but we think they are guilty of a most suicidal error. We were amused with an illustration of this idea we heard the other day. One of our most esteemed and illustrious photographic chemists was recently staying for a short time in an obscure rural village, when circumstances threw him into contact with a peripatetic photographer, who was taking cheap glass positives of the rustic Chloes. The pictures were fogging very much; and the *savan*, with the courtesy which characterizes him, asked some questions with a view to helping the portraitist out of the difficulty. The reply was discouraging: "Oh! that was all right enough; it would brush off when the portrait was dry!" To shorten the story, the operator had been a photographer fifteen years; he thought he knew a thing or two; but never read the journals; not he. He was quite content, after fifteen years' experience to take cheap glass positives, the fog on which might be brushed off when it was dry! We only give this as an extreme instance to illustrate our suggestion.

To return:—Another noticeable omission, and we must confess to ourselves a disappointing one, is the absence of portraits enlarged by the solar camera. There are two or three enlarged portraits, but as to the method of enlargement, the catalogue is silent. The most prominent of these, a portrait of Lord Macaulay, we have already noticed; further examination confirms the opinion we then expressed, and the universal comment we hear is to the same effect. It is highly valuable, as illustrating how one offence against the canons of artistic propriety and good taste is sufficient to spoil much, otherwise, skilful labour. This is a portrait in which, we doubt not, the photography was perfect, and the painting is well done, yet from the enlargement being to a size just less than life, the effect given is of an insignificantly diminutive man or an antiquated boy. An enlarged head, about half the size of life, exhibited by Lock and Whitfield, and finished in black and white chalks, is spirited and effective. There are a few other enlargements, unimportant either as to subject or method. We have seen some good enlarged pictures, produced by means of the solar camera, but we are sorry that nothing of the kind is here exhibited.

If size alone were a condition of excellence, perhaps the largest portraits (not enlarged) are those exhibited by Messrs. Baugh and Bensley. It is a pity that quantity cannot be accepted in lieu of quality; where the results, however, are bad, the badness seems offensive in the direct ratio of size. A portrait of G. P. Bidder, Esq., No. 208, notwithstanding the interest which attaches to the aforetime "calculating boy," the now able engineer, is an especially unsatisfactory portrait—a full-length standing figure of an apparently somewhat ungainly person, exhibited in the most ungainly aspect. Some portraits of Mr. Webster, in the "Dead Heart," are much better, being well lighted, well posed, and generally effective. All the pictures exhibited by these artists bear evident impress of the old hypo toning, and are already somewhat yellow.

No. 8, a frame containing seven portraits by J. G. Macandrew. These are all good photographs, and apparently pleasant portraits.

No. 17, a frame containing eight portraits by C. Wright. We are sorry for this artist that his works have been praised by some of the critics; there are some indications of a desire to produce artistic pictures; but there is as yet a considerable shortcoming of all the artistic excellence of which photography is capable, there is much that is hard and coarse about his pictures; which are, moreover, sulphur-toned.

Mr. Hering exhibits some very fine portraits. There is less that is common-place about these than among many other equally good photographs; the white background is in many cases a slight drawback.

No. 138 is a portrait by the Rev. Dr. Holden, coloured by C. Burlison, artist, Durham. What a tide of recollections does the name of the painter here mentioned bring across our mind! Years before the advent of photography he was just commencing his career as an artist of high promise in our native town, and, if we rightly remember, about to start for Rome to pursue his studies, at the time of which we speak. He had commenced life as a coach-painter, and we enthusiastically believed it to be worthy of the highest ambition to emulate his example, and would gladly have stepped on to the lowest round of the ladder to follow him step by step. We love the pencil still, although our duties bring us more into the dark-room than the studio, and more to the editor's desk than either. The portrait which has recalled these memories indicates how a clever artist may make an indifferent photographic colourist; unless, indeed, the position of the picture, right down on the ground, prevents us arriving at a just judgment, notwithstanding that we have repeatedly been on our knees to examine it.

M. Claudet exhibits some very fine portraits of a large size, graceful in pose and good in execution. Messrs Caldesi and Blandford, also, have some very excellent specimens, in which, notwithstanding a little redundancy in background accessories, a decidedly artistic taste is manifested. We commend the method of mounting these portraits to the attention of photographers. About an inch of a very delicate drab surrounds the picture and gives the effect of an engraving on Indian paper. We prefer the effect of the tint here used to that of India paper proper. The tint is produced, we presume, by lithography on the mounting board.

The Rev. T. M. Raven has some very pleasing portraits and *genre* pictures, in which general arrangement, pose and expression are decidedly good. A series of portrait studies by Mr. C. T. Newcombe, are hung in a bad light, but appear to possess much merit.

"Our Charley," No. 622, London Stereoscopic Company, is a pleasing portrait of a pleasant smiling boy in a reclining position. The portraiture is better than the photography, which is just a little hard.

Mr. R. F. Barnes has a number of portraits of unequal merit; a series of studies, No. 423, are the best specimens he exhibits.

The coloured portraiture is a striking feature of the Exhibition, one end of the room being chiefly devoted to that branch, and the wholesome rule,—at one time we believe held imperative,—of insisting on the exhibition of an uncoloured duplicate of each coloured picture, appears to a large extent abrogated.

Claiming precedence as the productions of a gentleman belonging to the very foremost rank of miniature painters, are the water-coloured specimens of Carrick, of which there are about thirty, many of them large pictures. We must fairly confess we are disappointed in them. With much that is very charming, they are, at least the major part of them, flat, feeble, and insipid. There is, moreover, an unaccountable family likeness prevailing amongst the sitters that is quite unaccountable. The interest attaching to the names of the various portraits is undoubted: we have Charles Reade, Charles Mackay, Fred. Goodall, A.R.A., Samuel Lover, S. W. Carmichael, with more artists, men of letters, and other celebrities; but we cannot understand why they should all possess in such a marked degree exactly the same tint of flesh, and the same, or nearly the same, stony grey eyes. The manipulation is throughout very perfect, and much truth, delicacy, and artistic feeling pervades the pictures in many cases; the silk and satin draperies are exquisitely painted, and are at the same time quiet and subordinated; the backgrounds, in some cases, especially the sketchy landscape backgrounds in vignetted pictures, are very beautiful, and display the true artist, but the faces are flat, and deficient in modelling, and the general effect of many of the pictures is feeble and unsatisfactory.

The oil-coloured photographs exhibited by M. Claudet do not generally err in the same direction, they are mostly brilliant, and many of them are exceedingly well painted; some of them are much too pretty to be artistic, and have unnaturally blue skies, glowing draperies, and waxy flesh; in the majority, however, the painter and the photographer have combined to produce a perfect whole.

Lock and Whitfield, as usual, exhibit some exquisite specimens of manipulation in water colouring, but there is also the same tendency to a slaty tone in many cases, with the same large eyes and faultless mouths.

Gush and Ferguson have some very fine specimens of water-coloured portraits. Maull and Polyblank show some oil-tinted portraits which are very chalky and unlike flesh. Mr. D. Mossman shows a frame of coloured portraits by a process to imitate ivory; the imitation is tolerably effective and the result pleasing: the portraits are apparently on paper.

Notwithstanding many of the faults of coloured photographs, there is more good portraiture and more truth than we ever saw in an exhibition of miniature paintings. The men and women do look like men and women, and not like the conventional figures which for ages passed current for them amongst all but first-class miniature painters.

THE SCOTTISH PHOTOGRAPHIC EXHIBITION.

First Notice.

There never was a more unfavourable season for the enthusiastic photographer than the spring and summer of last year. "The rain it raineth every day" was, during the whole season, a great fact, which admitted of no dispute, except when it poured, and if, perchance, the sun ever "stopped in his course to play the alchemist," he presented such a sloppy front, and was surrounded by so many discordant elements, as to defy even an operation in wet collodion. Spring is the most prized season of the year by the out-door photographer, on account of the sharp and defined outline which every object presents in nature, and also from the trees not being so thickly clad with foliage as to hide their individual forms, or obscure the numberless flickering lights which play at hide-and-seek amongst their leaves and branches; but the "merry spring time," as it is popularly called, was dropt out of the calendar last year, and a season of darkness and gloom substituted, which set at naught the best efforts of the most accomplished photographer.

Impressed with these considerations, it was with fear and trembling that we betook ourselves to the Exhibition of the Photographic Society just opened in Mr. Hay's Rooms, George Street, Edinburgh, but a cursory glance at once dispelled our fears, and satisfied us that the display, if it did not surpass, was worthy to be ranked side by side with any of its predecessors. This may be accounted for by several of the best productions being the fruits of previous seasons. Robinson's "Holiday in the Wood," for instance, we saw in London upwards of a year ago; but however that may be, let us be thankful for the treat set before us, without inquiring too minutely into the time when it was provided. One great feature in the present Exhibition is, that it contains fewer specimens of an inferior class than on any former occasion, and in consequence the average rate of excellence is more equal and better sustained; while Robinson's two pictures of a "Holiday in the Wood," No. 65, and the "Top of the Hill," No. 27, are specimens of a class which, in artistic feeling, grouping, and composition, as well as in truthful light and shade, is entitled to rank with the best productions of modern art. It was Rejlander, we believe, who first originated the method of printing from various negatives, as displayed in his admirable cartoon of the "The Two Ways of Life," which, besides containing some thirty figures grouped artistically, was embellished with a landscape background. Excellent as that work was, it wanted the vitality and sentiment with which Mr. Robinson has imbued the present compositions, and which constitute them—works of intellect.

As the crack pictures of the season, a short account of these beautiful works may be permitted. The "Holiday in the Wood" consists of a party of ten children enjoying themselves with all the zest and glee of youth on a wooded bank; the expression and character of the children are most natural and pleasing, as they weave garlands of wild flowers, &c. In the middle distance, two little girls are advancing, one of whom carries a basket; the younger has a timid expression, which is rendered with the greatest truth, and the whole subject is enclosed in a background of trees, through which the light pierces, and gives to the composition a strong and picturesque effect of light and shade. The boy in the foreground is especially remarkable for exquisite manipulation and artistic excellence. The grouping throughout is of the pyramidal form, and the pleasing disposition and arrangement of the figures leaves nothing to be desired. Who shall say after this triumph of photography to what extent the art may be carried in the hands of a man of artistic perceptions! The other picture—"The Top of the Hill," No. 27—is not less remarkable than the preceding. It consists of a single figure, that of a girl, who stands in an easy position, with one hand on her breast—a pitcher resting on the ground at her feet. The scene is supposed to be the top of an eminence overlooking a valley in which a river flows through a richly wooded champagne country till it is lost in the far distance. The sky is without a cloud, and the open daylight effect of the whole—exquisite gradation of tints, which so admirably convey the idea of distance—and general truth and delicacy of the composition, are truly wonderful when the difficulties in representing such a subject, of which only a photographer can have a correct idea, are taken into account. It is not pleasant to make disagreeable prophecies, but as photography has already in a great measure superseded the miniature painter, the time does not seem far distant when it may probably equally affect the painter of *genre*.

In portraiture, as usual, the Exhibition is much indebted to that eminent photographer Claudet, who has led the way in carrying that branch of art to its present high degree of perfection. His beautifully clear and brilliant style, so truthful in its delicate middle tints and expression of local colour and effect, is regulated by artistic knowledge and a fine eye for the graceful and beautiful. Two of his largest portraits hang below "A Holiday in the Wood," Nos. 66 and 67. In the full-length of a handsome lady in white muslin dress, the artist has succeeded in giving the delicate shading of the white dress with all the truth and subtlety of nature. Another exquisite example of Claudet is "The Pet," No. 570, a small full-length of a young girl in a fanciful costume. This is quite a gem in its way—the perfection of photography in exquisite manipulation, texture, delicacy, and taste. All Claudet's other portraits will amply repay the most critical inspection.

Of our own artists, Tunny and Moffat take the lead in portraiture; Dallas is also very good, but too dark in colour, and consequently neither so agreeable or effective as the others. Of Mr. Tunny's portraits those of Mr. Duncan M'Laren, No. 490, and Mr. Robert Allan, No. 488, are admirable specimens. The first is one of the best portraits we have ever seen; and Mr. Moffat's Professors Christison and Syme, Nos. 552 and 524, are no less favourable examples of his talent. The portrait of Principal Brewster is also extremely good, though scarcely equal to Claudet's. The portraits by an amateur, Mr. J. Ramsay L'Amy, are amongst the most creditable things in the rooms. They are excellent in tone, colour and effect, and have a look of life about them which is very pleasing. Mr. L'Amy also exhibits several landscapes that are equally satisfactory. His coloured portraits seem good photographs spoiled—though from no fault of the painter. The beautiful small compositions of Lady Mathison are always interesting. Four small groups, No. 32 *et seq.*, are artistically disposed and executed with taste and precission. Her "La Penserosa," No. 564, and "L'Allegro," No. 576, are also happy conceptions, and well executed. The studies of Mr. A. T. Herries in Guernsey, Bruntisland, &c., are this year distinguished by greater precision than formerly. Some of them are first-rate. Dr. Walker's two studies, Nos. 304 and 305, are picturesque bits, though scarcely expressed with that completeness we have seen on former occasions. "The Greenhouse," by Mr. George Moir, No. 470, and a study of an "Old Lady," by Mr. John Cay, No. 566, though both small, are highly creditable. The Russian portraits of Mr. J. M'Gregor, No. 252 *et seq.*, do not impress us with a favourable idea of Russian beauty—they are, however, well executed; and his "Finnish Egg Women," "Hungarian Tinkers," &c., No. 307, are curious. Mr. Horatio Ross is celebrated for his love of and proficiency in field sports, and displays the same taste in his selection of subjects for photographic representation. He may be termed the Landseer of amateur photography. The spoils of the chase are exhibited in four pictures, No, 300, and very careful studies they are, though we cannot say Mr. Ross has been quite so successful in his white hares as Claudet in his white gown.

The landscapes of Vernon Heath are amongst the most attractive in the Exhibition, and bright sunny scenes they exhibit. The execution is delicate and highly finished, and the subjects well chosen and tastefully handled, but the texture in its lightness is apt to diverge into muzziness; and had the execution been a little sharper we should have considered it an improvement. Mr. T. Annan's landscapes are all exceedingly clever and picturesque. No. 276, "Aberfoyle," is complete as a picture; and No. 280, "Inversnaid Waterfall," is equally good. In winter scenes, in architecture, and in portrait, this artist is equally at home, and his works rank amongst the best in the rooms. Mr. D. Campbell is also an able photographer. His "Culzean Castle," No. 101; "View on the Girvan," No. 378; and "Craufurdland Castle," No. 398, are all excellent specimens, and highly creditable to his talent. In architecture, the "North-West Door of Rouen Cathedral," No. 283, by Bisson Freres, shows the capabilities of photography for such subjects. In detail, texture, and relief this photograph is perfectly illusory, and the ablest of artists, with unbounded time at command, might despair to reach its truth and finished excellence. —*The Scotsman.*

DIALOGUE SKETCHES.—No. 6.—At a Photographic Exhibition.

[From a "Photographer's Common-place Book."]

"What would you have me do,
When out of twenty I can can please but two?
One likes the pheasant's wing, and one the leg;
The vulgar boil, the learned roast an egg:
Hard task to hit the palate of such guests."—Pope.

At a photographic exhibition, if you please, not this, nor that, no, nor t'other; but, to "prevent mistakes," at *a* photographic exhibition.

Among the people present at this exhibition are Lovetruth, Brushart, and Process; and they are examining a large specimen, in which the photographer, with a fine feeling for the picturesque, has successfully represented the mists and exhalations of early morning, floating upwards from the shadowy depths of a beautiful valley. In the foreground, a mass of foliage just catches upon its topmost boughs and sprays the gleams of the rising sun. The morning veil reposing in dewy heaviness over all, softens outlines and details in the middle distance, and gives to objects more removed a mysterious shadowy character, full of suggestive beauty for the imaginative and poetical spectator. It has a sky, but as that sky is natural, beautiful, and in keeping, I don't care one fig how it was got. It it is numbered in the catalogue 9,899, and is, in short, the identical photograph described as taken by Newart in the first of these sketches.

Brushart.—If I am so far won over to your opinion, Lovetruth, don't be conceited, for the fact is due rather to Newart's works than your words. But although I *now* admit that photography may secure form and its actual expression, I can never exalt the grossness of the mere material to a level with spiritual refinement and ideal beauty. In a fac-simile representation of nature it is, of course, as you say, impossible to separate the soul from the body it inhabits; but in high art it is not always a soul in existence within that body which is reproduced in our painting, but a soul created by ourselves, and infused into our work as a portion of our own intellectual individuality. This it is which we recognise as high art, not exactly the perfection of the judgment, the knowledge of principles, the education of eye and hand, or the manipulatory acquirements of mere experience. Such things may be valuable as the grammar of a language, and the power to write and speak it; but the thoughts conveyed, the beauty embodied, the lessons taught, and the good done, these alone constitute art in its noblest and its highest state of progress and refinement.

Lovetruth.—Do you not see how, in making such an admission, you separate high art from the means used in its expression, and so confine it to a purely spiritual existence without language or form? It is true that the art which speaks, in eloquent language, and eloquent sentiments, the poetry of an artist-soul, must rank higher than that which merely indicates the common thoughts of common minds, in the language of vulgar life; but then, as you have made it no longer a question of the means used, he who has the mind of an artist, be he photographer, painter, poet, or musician, may have legitimate claim to the name of an artist also, even though he fail lamentably in every practical application of these high arts.

Brushart.—That claim is not legitimate until its justice is clearly demonstrated. When the lofty qualities of a master mind find expression on paper or canvass, or in the eloquence of the mighty orator, I admit the claim to distinction; but I can't praise the dumb for eloquence or admit the symmetrical beauty of a form I never knew.

Lovetruth.—Nor do I ask you to do so. If high art springs from the brain of the artist, rather than the process which expresses it, let photography be judged thereby. Here, for instance, is Newart's picture, and Newart is an artist. You will not deny that he chose this view with an artist's eye and a poet's feeling. It embodies all the thoughts to which it gave rise. It speaks to you and me, just as it spoke to him, and, therefore, may be as legitimately said to embody the intellectual emotions of the photographer's mind as any other work of art does the spiritual effort to which it owes its being.

Crackdbell (who has stolen up unobserved.)—It embodies a consumately good, practical knowledge of photographic chemistry, an excellent lens cleverly managed, a good process, delicately careful manipulation, and—*nothing else.*

Process.—Well, well, I won't go so far as that; although, of course, such things as Crackdbell names, are the most important, because it is clearly impossible to produce an artistic picture if you have a bad lens, an inferior process, or don't understand the management of your chemicals. Still I think the mind of the artist necessary to produce the highest results, although he must *first* be a good photographer. Now, look here (pointing to a photograph numbered 9,840), that's a splendid photograph, and an artistic picture to boot; but it wouldn't be the latter if it were not the former. What do you think of it, Brushart?

Brushart.—Hum! not *too* much.

Process.—Indeed! Well I am surprised! Why look how sharply defined it is even in the extreme corners, how full of detail and sharpness the distant objects are. There is nothing lost either in lights or shadows, and— but what do *you* think of it, Lovetruth? Brushart here only believes in art which is created with the brush.

Lovetruth.—It really is a most ingenious performance. The photographer must have taken an infinite amount of pains. However he contrived to get so much sharpness in distant objects confounds me—

Brushart (aside).—And ærial perspective.

Process.—Ha! ha! I thought it would please *you.*

Spectator (examining the specimen in question through a powerful glass.)—Lor! bless my heart! Isn't it wonderful! I do believe I can, through this glass, see the time at which it was taken by the clock in that very distant church tower!

Lovetruth.—How anxiously such an operator must watch for a clear and cloudless day, when the pure atmosphere is almost colourless; what faith he must have in stops, and what delicate manipulation and mechanical skill he must adopt to succeed in so wonderfully violating all the truth and beauty of nature!

Process.—Hey, what! *you* don't like it? Well!

Crackdbelt.—Like it, why how could he like it?

Process.—No, I forgot; it ought to be out of focus, like that hazy, indefinite, foggy-looking mass of indistinctness and folly you have been so comically praising for these last five minutes or more, much to my amazement and disgust; yes, disgust is the word, and so its out; excuse my bluntness.

Lovetruth.—My dear fellow, don't grow warm. We admire that hazy indistinctness, not because it indicates that the lens has been put out of focus, but because it expresses a certain atmospherical effect which we consider very beautiful. Such an effect might be out of place, and then we should condemn it, or unnatural, and then it would be ridiculous; but being both natural and beautiful we—as you say, "comically praise it."

Brushart.—Bye-the-bye; it strikes me that it would be a very effective way of securing softness, that.

Crackdbett.—That? what?

Brushart.—Why putting the lens a little out of focus.

Process.—Ha! ha! ha! I thought so.

Lovetruth.—That's a mistake Brushart, but it is one into which others have fallen. Sir William Newton, an artist and an enthusiastic lover and practiser of photography, pained by the hard unnatural effect of the photographs he then saw, could suggest no better method of destroying it than that of putting the lens just a *little* out of focus. But he knew as well as you and I that softness was a question of *gradation*, and that to put the lens out of focus was to impoverish and weaken the image; only it was the best remedy then at hand. Softness and hardness are qualities over which your lens should exercise little or no control. If I over-expose the image, I lose detail and gradation, and gain hardness. If I over-develope, I do the same thing. Some collodions won't give softness, some developers destroy it. In brief, we have so much control over our practical appliances that for every bad picture I hold its producer alone responsible.

And so they pass on to other pictures, criticising and arguing as they go.

Spectator No. 1, (coming up to Newart's picture).—What a wretched thing. Let's see, (looking at his catalogue) No. 9,899—Newart—Yes, a very poor operator, his productions are so very inartistic.

Spectator No. 2.—Yes, truly! what a pity these photographers are not artists. *That's* about the only artistic picture in the room, (pointing to 9,840).

Spectator No. 3 (*examining* 9,840).—Ah! you see, very beautiful as a photograph—*very*, but just imagine what a painter would make of such a scene. We should not have in his productions this hard flat effect—this want of space and air—this uninteresting monotony of subdued tones—this harsh hardness of lines and horrible distinctness of detail.

Spectator (No. 3's companion).—Ah! but you mustn't compare photographs with paintings, you know; it is not fair to do that. Of course they have their value, and in some branches that value is really very great, but they can never rank with works of art. Why, bless you, my chimney-sweep* takes photographs now, and very nicely he does them too. I gave him the ridiculous sum of fourpence for a picture which my wife prefers to one which cost me a guinea.

Spectator No. 4.—Ah! effect of morning mist. Beautiful, beautiful, very beautiful!!

In publishing the last of this series of "Dialogue Sketches," permit me to add a few remarks in my own person. These motley papers of mine have advocated a much neglected branch of the photographic art; and in these sketches, I have particularly endeavoured to draw more closely together the ties which unite the photographer and the artist, confident that their union must benefit both. In earnestly advocating the artistic in its practical application to photography, I have only endeavoured to give it a fair amount of importance in its relationship with all the other branches of photographic art and science; and let no one imagine that I have attempted to elevate one by the degradation of another. I introduced Lovetruth and Newart to personify the photographic-artist and the artist-photographer; Brushart to represent those critics who believe in no art but their own Process as the advocate of "purblind practice" and mechanical photography; Snailowl as the old-fashioned—if I may use such a word in connexion with so new an art—the old-fashioned photographic conservative, precious slow in his progress, and anxious "to keep it dark;" and Crackdbell, whose name the following lines will give good reason for, because he

> "Like a bell that *time* hath crack't,
> Which by this certain mark is known,
> His speech is clatter without tone."

My Common-place Book will find me other papers or other texts; but for a few weeks to come I shall confine myself to a series of articles, which I trust to render of good practical service to all who are desirous of blending the artistic with the scientific in their photographic manipula-

* See "Talk in the Studio," vol. v. p. 48.

tions. I refer to the "Technology of Art," now in the course of publication. Good artistic pictures will do more to elevate our art in public estimation than all the writing and talking of our journals and societies, although to that talking and writing, if we are only practical, such results may be primarily due. I have, therefore, much pleasure in adding my mite in the the cause of artistic photography. A. H. W.

Scientific Gossip.

Some comparisons of the relative intensities of the moon with Jupiter, Venus, and the sun, have recently been made by Professor Bond. He has found that the light of Jupiter seen from the earth at its mean opposition is to the light of the mean full moon, as 1 : 6430. Compared with the light of Venus at its greatest brightness it is as 1 : 1·4864. Thus the moon is equal to 6430 Jupiters, all shining in the heavens at once, whilst it would require nearly 1½ Jupiters to produce a light equal to that of Venus. Comparisons between the brightness of the sun and moon had previously been made by Bouguer and Wollaston; the former found that one sun was as bright as 300,000 full moons, whilst Wollaston considered that it required 801,072 full moons to equal the sun in brilliancy. The preference has generally been given to the latter. Professor Bond has just completed a series of experiments on this subject, and adduces several reasons for considering Bouguer's method of observation to be the best of the kind, and his results deserving of most confidence. Amongst other experiments tried by Professor Bond was one in which comparisons by means of Bengola lights, were made between the images of the sun and moon reflected from a silvered globe. This gave the value, sun=471,000 moons. Other methods less reliable also tend to confirm Bouguer's determination These results will serve to convince photographers of the hopelessness of attempting to take photographs by moonlight, as we know has more than once been attempted and frequently proposed: for taking that measurement which gives the least difference between the sun and the moon, and supposing that a sensitive collodion film only required one second's exposure, it would then require to be kept in the camera, looking at the landscape, for 300,000 seconds, or upwards of 83 hours. And not only must the 83 hours be only moonlight, but it must be that of the *full* moon shining on the object under the most favorable circumstances.

In a former "gossip" we gave an account of an apparatus made by Mr. Gassiott for the purpose of producing light without any accompaniment of heat, by means of an induced current of electricity, and suggested the employment of this kind of apparatus for surgical operations, &c. We are glad to see that Mr. W. Hart, a surgical instrument maker of Edinburgh, read a paper on this subject at the last meeting of the Royal Scottish Society of Arts, and exhibited the instrument before the meeting. The arrangement consisted of a small Ruhmkorff's coil machine capable of working with a small battery, and transmitting electricity through narrow glass vacuum tubes, bent near the middle until the ends come nearly together. When a stream of electricity is passed through one of these tubes from the coil, especially if the tube contains a rarified medium of carbonic acid gas, a stream of constant and mild light is emitted from the tube, which can be introduced into any cavity or recess where light is required, and observations can be made and operations performed without interruption from the shadow of the operator, and without the use of reflectors. The value of this light is greatly augmented from the fact that there is no danger of scorching the patient, as there is no perceptible degree of heat resulting from its use. These tubes can be constructed of almost any shape and size, according to the nature of the operation required, and the colour of the light can be adapted to the same object according to the character of the gas introduced into the tubes. Two small Bunsen batteries are sufficient to produce a light sufficient for all ordinary purposes. To the photographer this new light is of almost as much importance as to the surgeon The number of actinic rays it contains is something astonishing, being almost equal to the flame of sulphur burning in oxygen. There is no difficulty whatever in arranging the light; in fact, when once the instrument is adjusted the light manages itself, and will keep glowing night and day without attention, so long as the battery power is maintained. The expense at present would be undoubtedly considerable, so much so, in fact, as to entirely preclude any but the very wealthy from employing this means of night illumination; but in this it only shares the same fate with most novel discoveries; as soon as public attention is directed to the many advantages to be derived from "cheap electricity," there will be no lack of companies to supply the want, or of experimental and mechanical ingenuity at the service of the companies. The means of obtaining cheap electricity do exist, they only want economical application on the large scale.

The beautiful method of spectrum analysis, to which attention has recently been drawn by MM. Bunsen, and Kirchhoff, seems to be producing good results. A short time ago we had to announce to our readers the discovery of a new metallic element by its means, and we have just now heard that another metal has been added to the number. Messrs. F. W. and A. Dupré have found in some deep well water of London a fourth member of the calcium group of metals. It gives but one line, an intense blue one, and, as far as is known at present, seems to resemble calcium in its properties.

After the continuous bad weather with which we have been favoured during the last 18 months, it will be some consolation to know what we have to expect in future, and this, after reading an account of some investigations by M. Renou, does not seem quite such an impossibility as it is usually supposed to be. In January last this gentlemen sent a paper to the French Academy of Sciences, in which he showed that severe winters followed each other in groups of five or six at a time, and generally recurred in nearly the same order of severity in the course of a period of 41 years. The same meteorologist has now, in a second paper, endeavoured to unravel the mystery of the recurrence of warm summers. These he finds easier to characterise by their mean temperature than by their extremes; he establishes six groups as follows:—very warm, 20° C.; good, 19° C.; middling, 18° C.; bad, 17° C.; very cold, 16° C.; exceptional, 15° C. Still there are more difficulties to contend with in classifying summers than in the case of winters. Thus the summer of 1834 was very warm at Paris and Berlin, and cold on the contrary, at Orange, showing a great variation within a comparatively small surface. Also owing to difference of exposure and want of corrections, old observations are less reliable in the higher than in the lower temperatures. As far as M. Renou has been able to judge, the period of 41 years is not so apparent in the case of summers as in that of winters; but the former seem to recur immediately after the expiration of the period of severe winters. The other seasons appear to be more easily amenable to the period of 41 years. M. Renou notices some curious coincidences: thus the minimum temperature of the year 1805 occurred on the 18th of December, and in 1846, on the 19th of the same month. In the year 1806 the same minimum fell on the 12th of March, and in 1847 on the same day. In both cases it will be remarked, the interval of 41 years is the same. It is also a singular fact that the period of 41 years is precisely that which seems to belong to the return of the solar spots.

A new use of the photographic element *par excellence*, iodine, has just been announced by M. Commandeur, that of attracting together slugs and snails. Some time ago he accidentally left in his garden a vessel in which he had been making experiments with starch and iodine; this vessel, imperfectly covered with a bit of board, remained exposed to heat and rain for the space of three weeks. At length it one morning attracted M. Commandeur's attention, and upon examination, he was surprised to find it occupied by dozens of snails and slugs, which it seems had congregated there from every corner of the garden. The experiment was continued, and became apparent that the emanations of iodine will attract these creatures from a considerable distance, when they may be destroyed by hundreds.

DISCUSSION ON ALBUMENIZED PAPER AND ALKALINE GOLD TONING.

OPENING PAPER BY C. JABEZ HUGHES.*

The usual mode of opening a discussion is to apologise for the subject, and to depreciate oneself for bringing it forward. I am sure you will excuse these conventional formalities, for no plea need be urged to establish the importance of Good Printing.

All our other processes are but preparatory steps to printing. For that we make our pyroxyline, prepare our collodion, purchase our apparatus, and rack our brains to produce perfect negatives. With this object before us we travel o'er land and water, climb glaciers, face water-falls; on mountain top, in sheltered valley, on open heath; in deep forest, or dark glen—wherever, or to whatever we point our lens, this is the consummation we always have in view—the reward for all our labour.

If not the *be all*, printing is certainly the *end all* of our various processes. It is the last crowning stone of the edifice —the very apex of the pyramid.

Yet, with all its importance, we do not do it justice. We vote it a bore, we declare it drudgery, delegate it to our assistant, put it out to be done, employ ignorant men, silly women, and foolish children to do it. We hurry it over, begrudge the time, stint the money, use the cheapest materials, and, finally, inconsistent beings that we are, express astonishment that our results are not uniformly of first-rate order.

Note the different degrees of care with which the two halves of the photographic process are conducted. For our negatives we obtain the best glass, prepare it most scrupulously, and do not dare to touch its clean surface; but our boy lets the albumenized paper lie about anywhere, and he fingers it and "paws" it all over. Our collodion we pay whatever price the celebrated maker asks for it, so that it be up to the right standard, and we watch and study it as to its age and condition; but send here and there, anywhere for our paper, and generally with an eye to cheapness.

We should not dare to keep three or four sorts of collodion, and jump from one to the other, and expect at once to get equally good negatives; yet we employ different samples of paper, treating them all alike, expecting they will or ought to "come out" equally well, and without hesitation condemning them if they have not answered our expectations. We know that different kinds of collodion require different baths and developers, and variable manipulation, but we have yet to learn that different papers require their special treatment too. In our negative bath we use the purest recrystallised or fused nitrate, but anything will do for printing. We make up one bath with religious care, and most jealously watch its condition, but the other may take care of itself. It is 60-grain to-day, may be 40 to-morrow, and the day after, in a fit of generosity, may be strengthened to 70. This week it is acid, next it may be alkaline; but too generally it may be what it likes and how it pleases.

There are many photographers who really do take pains, and study the production of their prints as carefully as their negatives, and they have their reward; but the majority do not. These latter treat the operation as if it were mechanical, instead of chemical, and expect it equally readily to be despatched. The very term "printing," by the association of ideas, helps to confirm the mechanical notion. The letter-press printer bestows all attention on the skilful arrangement of his types, the engraver on the cutting his plate, the lithographer with drawing on his stone, and wood engraver on the block; this well done, the rest is only careful "working off," or "machining." But photography is not mechanical, and will not be "machined." The simile holds good between the composing the types and making the negative, but it wofully fails after; for every photographic print is the result of a series of delicate chemical operations, and if the result is not as we wish, we must endeavour to discover where the error creeps in, and either by alteration of manipulation or variation of material produce better results. If photographers would but look at prints as chemical, not mechanical, products, and endeavour to grasp the causes that produce them, from that moment their prints would be improved and their effects more uniform.

With relation to present troubles, most of them are based upon and grow out of that fatal facility of production that was in use during the sulphur-toning period. It was necessary then only to take the print out of the pressure-frame, and immerse it in the inky hypo; and there it remained until it was "done." The present method requires much more care and attention, and by some this is given grudgingly; they shirk the proper preliminary washings, and, getting into trouble, of course, blame the process. Sulphur as a toning agent was not very delicate; much or little albumen, or none at all, it was chiefly a matter of time, and he served all prints alike; whether the paper was thick or thin, English, French, or German, he toned them all the same; like a specious, plausible, malignant, destroying demon as he was, his *in*-justice was impartial.

But our present protecting genius, Gold, is much more nice and delicate, and recognises most critically the differences of much or little albumen, of the various kinds of paper, and of minute variations of manipulation. We are now in a transition state, and shall doubtless yet arrive at a perfect toning process, which will be uniformly certain, but we must throw away some of our past notions, and not say what albumenized paper and gold *ought* to do, but what we can obtain from them. They will not yield, so we must.

Too many of our printing notions depend on those conceived during the sulphur-toning period. There is a tendency to depreciate the application of those careful rules that we apply to the production of negatives. The printing process is almost supposed as if it ought to be automatic—self-working. I don't know why we ought to assume this. It would be very desirable if it were so; but at present it is not.

In the practice of negative-taking, we are not surprised if a goodly number are not first-rate; but our prints, about which we take so little pains, ought all to be perfect. We calculate how much we can get out of a sheet of paper, and expect every square inch to turn out right.

The drift of my observations is to show that we ought not to expect to produce good prints uniformly, unless we take great care, and study attentively the conditions under which they are best produced. If this be done, I am sure we shall fail less often. We must expect less from our materials, and more from ourselves.

We depend far too much on special formulæ, acting too frequently to the letter, instead of the spirit. For example, in Maxwell Lyte's toning process by phosphate of soda and chloride of gold. In his directions, he says, employ *neutral* chloride of gold. Well, in commerce, the article is called neither acid chloride nor alkaline chloride, but simply chloride of gold; and the majority of operators assume, therefore, it is neutral, and add it to the phosphate; and being, as it always is, more or less acid, mostly the former, phosphoric acid is liberated in proportion to free acid in the gold, and a different result is produced to

* Read at the meeting of the London Photographic Society, Feb. 5, 1861.

what Mr. Lyte intended, and, of course, the process is all rubbish. Again, I have found persons toning with acid solutions of chloride of gold, when they believed they were working with alkaline; they have added the modicum of carbonate that their formula prescribed; but whether it was sufficient to neutralise the free acid always present in the commercial chloride, is a point they have never tried. A given method may work well with one kind of paper and not another. One man may produce uniformly hard negatives, and require a paper to give a soft image; whilst another gets little contrast, and must force it out in printing. In one district the water is soft and pure, in another very hard and limey; and shall one formula be applicable under all circumstances, nothing be left to the skill of the operator? and if the process fails, is the man wholly blameless?

Although the laws of chemistry are regular and certain, yet who can anticipate or give directions to another how to act under every emergency? The man who depends exclusively on formulæ, who does not grasp the spirit as well as the letter of instructions, will always be liable to derangements. I make these remarks because I so frequently hear paltry and foolish objections urged against processes and formulæ; men should take up subjects large-heartedly and frankly, and not be discouraged easily, work themselves out of their difficulties, and not allow success and failure to depend so much on external circumstances.

(*To be continued.*)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 6th February, 1861.

Among the photographic curiosities at present exciting the interest of the scientific world, may be mentioned a photographic copy of a portrait of Kepler, the father of modern astronomy. This portrait, for some time lost and forgotten, is supposed to be the most faithful likeness of the great astronomer extant; it was given by him to his friend Matthew Verner, of Strasburg, who bequeathed it to the public library of that city. This interesting and valuable picture is unfortunately in a very bad state of preservation, and the photograph cannot, as a faithful copyist, but render its defects. At the same time it is good enough to give a very favourable idea of the noble and agreeable features of the original.

Mr. Persoz proposes a new method of analysing saltpetre. The foreign substances usually mixed with nitrate of potash are, 1st, water; 2nd, matters insoluble in water; 3rd, chlorides; 4th, sulphates. The quantitative analysis of these substances is conducted in the following manner:—

Separation of the water.—The saltpetre is dried in a platinum capsule, which is then heated to the temperature at which the salt begins to fuse. The difference in weight indicates the quantity of water.

Separation of insoluble matters.—The saltpetre fused as above is dissolved in a given quantity of water. The solution deposits a residuum which, collected on a filter previously weighed, and which, weighed again after being well washed and dried, gives the weight of the insoluble matters.

Separation of the chlorides.—The filtered solution, which we will call N, separated from the insoluble matters, is precipitated by nitrate of silver in the same manner as silver is analysed by chloride of sodium. Thus, a silver test-liquor serves to determine the chlorides in the same manner as a test-liquor of chloride of sodium serves to determine the quantity of silver. If bromides or iodides exist in the saltpetre, they are thrown down with the chlorides, which is of no consequence in this analysis. These salts are rarely present, and never but in very minute quantities.

Separation of the sulphates.—This part of the analysis presents some difficulties, on account of the property possessed by the insoluble sulphates of dissolving in the alkaline nitrates. In one litre of water dissolve 259·8 grammes of pure well-dried chloride of barium: each cubic centimetre of this solution will contain 0·258 gramme of chloride; consequently, it represents 0·179 gramme of sulphate of soda, and 0·208 gramme of sulphate of potassa. Measure 200 cubic centimetres of the solution N, prepared as above; and after acidifying it with pure nitric acid, put it into a platinum crucible, and make it boil; then add it little by little to the test barytic solution, until the latter is no longer clouded and remains in excess. Arrived at this point, an alkalimetric test-tube is filled with the liquor N, which is dropped into the capsule containing the barytic solution, to neutralise the excess of the baryta.

Separation of the nitric acid.—Although the preceding operations may suffice, and, in knowing the quantity of water, and of the chlorides and sulphates, the nitrate of potassa can be calculated by the difference; but the nitric acid may be tested directly in the following manner: take, for example, a quantity of saltpetre representing two grammes of the salt deprived of water, the quantity of water it contained being previously ascertained; add to these two grammes of saltpetre, a quantity of the solution of bichromate of potassa containing exactly four grammes of this salt crystallized; the saltpetre is dissolved in this liquor, and the whole evaporated in a platina crucible previously weighed. When the two salts become dry, and the heat begins to melt the mixture, a very vivid reaction ensues, and abundance of nitrous fumes are given off, at the same time the chromic acid seizes upon the base of the nitrate. When we are sure that all the saltpetre is decomposed, the crucible is left uncovered, to admit of the absorption of the air, and when it is cold it is placed in a scale. The diminution of weight observed represents exactly the weight of the nitric acid contained in the saltpetre analyzed. For example: weight of crucible thirty grammes; nitre to be analyzed, supposed to be dry, two grammes, bichromate of potassa, four grammes, total thirty-six grammes. If, after calcination, the crucible weighs only thirty-five grammes, it shows that one gramme of nitric acid has been separated from the saltpetre, the weight that will represent the quantity of nitric acid it contained.

Benzine is employed with good effect in insecticide. Insects are instantly asphyxiated by it, and a remarkable effect resulting from the kind of intoxication benzine produces is the rigidity assumed by various insects subjected to its influence, particularly the lepidoptera. One or two drops of benzine is sufficient to give the finishing stroke to the largest insect of our woods and fields. The rigidity is so great, after death, that the wings of a *libellula*, if touched, bend, rather than break. The *diptera*, whose flight, although due to two wings only, is so energetic, exhibit analogous phenomena, especially the two species *musca vomitoria* and the *cristalis similis*, legions of which hum amid the flowers of our gardens and the leaves of the forests. It is singular, that the next day after the benzine has done its work, and has evaporated, the suppleness of the articulations is restored. It is said that even rats and mice quickly disappear from a place in which a few drops of benzine are sprinkled.

THE ALBUMEN NEGATIVE PROCESS.

Sir,—I mentioned in a previous communication on this subject, that the process I employed, was that described in your columns by Mr. Archer, but as his letter is in another volume, I will, at your request, give a very brief outline of the formula as I use it, and by which a satisfactory picture may always be obtained.

1.—Coat the plate with—

Albumen (one egg)	1 ounce
Syrup	½ „
Iodide of potassium	7 grains
Bromide of potassium ...	3 „

[The syrup consists of 1 lb. of loaf sugar to half a pint of water, boiled for a few minutes.]

The above quantity will be sufficient for some thirty plates, stereoscopic size, and should not be used till at least three days old. It may be used over and over again till the last drop, care being taken to filter each portion before pouring it on the plate.

2.—Thoroughly dry the coated plate over a spirit-lamp, or a gas-jet, draining off the surplus on a piece of clean blotting-paper.

3.—Insert for half a minute while *warm* (not *hot*) into a bath of—

Nitrate of Silver	45 grains
Acetic acid	1 drachm
Water	1 ounce

4.—Wash well with common water.

5.—Insert for about a minute into a pan containing two grains of common salt to the ounce of water.

6.—Wash thoroughly with common water,—the more the better.

7.—Dry, first spontaneously, and then by gentle (not excessive) heat before a fire.

Plates so prepared will keep quite unimpaired during a month; I have never tried them longer.

Develope in a pan containing sufficient just to cover the plate, of—

Gallic acid	6 grains
Water	1 ounce

with the addition of ten minims of a five-grain nitrate of silver solution to every ounce of developer. A properly exposed picture will require no more silver, and will be completely developed in about two hours, without any further attention being paid to it.

If it be desired to develope more quickly, first moisten the plate with clean water, then use—

Pyrogallic acid	1½ grain
Citric acid	1 ,,
Water	1 ounce

with the addition of five minims of the five-grain silver solution to every drachm of the developer. The picture will appear in about five minutes, and the development will be complete in about ten minutes. A little more silver may be added, if necessary, when all the details are out, but it is seldom required.

I should add that it is stated that gallic acid with acetate of lead is preferable to either of the above developers, but it has not proved so in my hands.

By a typographical error in my letter which appeared in your impression of January 4th, my meaning is reversed. The passage stands, "I think these methods cannot be considered properly, as they have been hitherto termed modifications of the Fothergill process," &c.; my argument was that the "Taupenot" was an albumen process, and, for reasons that I detailed, I thought that the several methods of Messrs. Petschler and Mann, and Dr. Ryley, "cannot be considered properly, as they have been hitherto termed modifications of the Taupenot process; but that they are rather modifications of the Fothergill process, which is, in the proper sense of the term, a collodion dry process." As I consider this distinction is important, I shall be obliged if you will permit this correction to appear.—Yours faithfully, F. Richards.

Proceedings of Societies.

London Photographic Society.

The annual meeting took place on the evening of Tuesday, February 5th. C. B. Vignoles, Esq., F.R.S., vice-president, in the chair.

The minutes having been read and confirmed,

The Chairman explained to the meeting that, owing to the delicate state of Sir F. Pollock's health and the claims of his parliamentary duties, he was unablo to attend the meeting. The first business now before them was the election of officers for tho ensuing year. In accordance with Section VII. of their rules, any member having any additional names to propose besides these nominated by the council should have done so at the previous meeting. No names having then been proposed, none were now eligible. Whilst the report was being read, the ballot-box would be passed round, and members would drop in their papers.

A Member asked if the lists of names nominated by the council had been sent round to members.

The Chairman said they had been published in the *Journal*.

A Member would have been glad to have had the addresses of the gentlemen proposed, with a view to ascertaining whether they resided in town or country.

The Chairman said the rules did not specify that the officers should be resident in town.

Mr. Le Neve Foster said, that of the five gentlemen proposed for election as members of the council, four were resident in town; and the president, vice-president, and treasurer proposed were all three resident in town.

Mr. A. R. Hamilton, in the absence of Dr. Diamond, then read the report of the council and the balance sheet for the year.

The Chairman said it would now be necessary to appoint two scrutineers to examine the papers, some of which, from not being properly folded, had got by mistake into the negative box.

A Member (Mr. Sedgwick, we believe) said, that this was a perfect farce of an election.

The Chairman said, if any member had wished to propose other members, he ought to have done so at the December or January meeting; none having done so, no other gentlemen but those nominated by the council, and whose names had been sent round, were now eligible for election.

Mr. Sedgwick: And for this reason it was a farce to send round the ballot-box, when there was no choice possible.

The Chairman then announced that Sir F. Pollock, F.R.S., Lord Chief Baron, was re-elected as president, Professor Bell, F.R.S., was elected as vice-president; and A. R. Hamilton was re-elected as treasurer. The gentlemen elected as members of council were—The Earl of Caithness; Warren De la Rue, F.R.S.; Walter Hawkins, F.S.A.; Rev. J. R. Major, F.S.A.; and T. R. Williams.

The gentlemen retiring were Roger Fenton from the vice-presidency, who takes the seat of Professor Bell at the council; and from the council, Messrs. Hardwich, Mackinlay, Marshall, Pollock, and Wenham.

The Chairman said, the adoption of the report had been moved and seconded, if any gentleman had any questions to ask or remarks to make upon it, now was the time.

[We hope to be able to give a copy of the report in our next; but in order to make the remarks which follow intelligible, it is necessary to state that, in referring to the death of the late Peter Fry, his early labours in photography, and his association with Mr. Archer in the early history of the collodion process, allusion was made to the part he took in resisting the claims of Mr. Talbot, who was referred to as wishing to patent the use of the sun altogether.]

Mr. Malone could hardly allow such a report as they had heard read to pass without some comment. In that report allusion was made to the late Mr. Fry, and in passing a just tribute to his memory reference had been made to past circumstances, which had involved a good deal of unpleasant feeling. He referred to the allusion to Mr. Talbot's claims. The report did not give a proper account of the transactions referred to, and he must say it was conceived in a partizan spirit. He had hoped that spirit had died out, and but for the present manifestation of it he should have been silent. It was stated, in the first place, that Mr. Fry had begun his work in connection with photography before the results of Mr. Talbot's experiments had been developed. That was a gratuitous remark; an attempt to exalt Mr. Fry at the expense of Mr. Talbot.

The Chairman said he must interpose to suggest that good taste should prevent these allusions to Mr. Fry, who was now dead. There was a good maxim *de mortuis nil nisi bonum*.

Mr. Malone said that the maxim quoted was doubtless a good one, but every one must judge for himself of the right application of it. This was not a question of good or bad taste, but of historical fact; and to correct the error of the roport in this respect was his only object. He wished to say nothing whatever that could be regarded as offensive to Mr. Fry. H i remarks were entirely directed against the report, or the writer of the report, for bringing these names into collision. The statements made in the report were not true. It was alleged that Mr. Talbot's object was to patent the use of the sun itself.

The CHAIRMAN would not allow such an observation to be made. It was not true.

Mr. MALONE took down the words at the time. It was distinctly stated that Mr. Talbot's object was to patent the use of the sun altogether.

The CHAIRMAN, on referring to the MS., said the words were there, but the essence of the thing was altogether different.

Mr. MALONE said the reference to Mr. Talbot was altogether gratuitous; he had made no such claim.

The CHAIRMAN.—It does not say he did.

Mr. MALONE must be permitted to reiterate that the statements made in connection with Mr. Talbot's name were most invidious, and appeared intended to cast odium upon him. The question was whether Mr. Talbot was entitled to take out a patent for his invention or not. In reference to the trial referred to he was not going to reopen the question, but he must remark that he was present at the trial, and the subject was not put by the judge correctly before the jury. If it had been—

The CHAIRMAN could not allow these remarks to be made.

Mr. MALONE said his remarks might appear invidious, and, but for the partizan spirit displayed in the report, he should not have made them. Mr. Archer's name was introduced into the report, and even if a man were dead, his name should not be made use of to cast odium on the living without calling forth a reply.

The CHAIRMAN would not allow this allusion. Mr. Archer was not named in the report, and he would not permit these remarks. He was sure every man would join him in protesting against it.

Mr. MALONE said that Mr. Archer's name was introduced into the report, and for the purpose of contrasting it with that of Mr. Talbot. However much averse he might feel to make these remarks, since the subject had been referred to, he could not permit Mr. Archer to have more credit than he deserved, and, in reference to the publication of the collodion process, Mr. Archer had said to him, when sitting beside him in one of their meetings, that "if Mr. Talbot and he had put their heads together they might have made a nice thing of it."

The CHAIRMAN again said he must stop these remarks; no one had shown such a spirit but Mr. Malone.

Mr. MALONE said his remarks had been provoked by the unjust allusions of the report.

Tho CHAIRMAN thought it was in very bad taste.

Mr. MALONE said it was simply a question of truth and justice. He had not only a right, but it was his duty to make these remarks. No one present knew so well as himself all the circumstances, and he felt it to be his place to defend Mr. Talbot from the unjust aspersions of the report.

The CHAIRMAN said it was the general impression that Mr. Talbot did throw obstacles in the way of the art's progress.

Mr. MALONE wished then, from his knowledge of the facts, to remove that impression.

The CHAIRMAN.—Mr. Talbot's proceedings cast a deep stain upon his name at the time. It was true he retracted somewhat afterwards, but the general feeling was against him at the time.

Mr. MALONE, as a party to all the arrangements at the time, must repeat that Mr. Talbot never wished to throw obstacles in the way of amateurs using his process; he only made it a condition that they should not practise it for profit, and this he was bound to do to protect the rights of his licensees. He felt it his duty to assert these facts, and reply to the remarks casting odium on the name of Mr. Talbot. If he appeared warm he assured the meeting it was more warmth of manner than asperity of feeling. He would not move any amendment to the report, but would content himself with the clauses referred to.

The CHAIRMAN thought his purpose would have been better answered by a few words without that animus, which all must deplore, much as they respected him. For his own part he had listened with great pain.

The report was now put to the meeting and carried.

The CHAIRMAN said, before calling upon Mr. Hughes, who was to open the subject of albumenized paper, he would call the attention of members to some wood blocks on the table, on which were photographic impressions ready for the engraver. They were executed by Mr. Thomas Bolton, and brought to the meeting by Mr. Delamotte. These photographic impressions were upon the prepared wood, the lights of the picture showing the white preparation on the surface, and not the mere surface of the wood. Mr. Bohn laid upon the table for inspection a copy of a new edition of "Jackson's History of Wood Engraving," which contained two of the blocks photographed and engraved by Mr. Bolton.

Mr. HUGHES read a paper "on Albumenized Paper, and Alkaline Gold Toning" (see p. 66). He prefaced the paper by saying Mr. Hardwich's object in proposing the discussion of the subject of albumenized paper and the troubles experienced in toning it with alkaline gold, was, not merely to have the opportunity of expressing his own opinion, but of eliciting the ideas of other members, so that by a comparison of experiences, if possible, to elicit some facts that might aid in removing these troubles. The distinct purpose, therefore, is discussion; and it is to be desired that members will be induced to take an active part in it. Mr. Hardwich asked me to open, and, fully reciprocating his wish that we might have not merely a paper from him, but a discussion among ourselves, I consented, and am, therefore, here without the usual announcement. My object is merely to open the subject by such general considerations that will invite others to follow, throwing out suggestions for you to embody.

At the conclusion of the paper, which was repeatedly interrupted by applause, the meeting gave hearty vent to their admiration.

The CHAIRMAN, on proposing a vote of thanks, remarked that the meeting could not but be greatly obliged to Mr. Hughes for the great good sense, striking illustration, and combination of wit and wisdom his paper displayed.

Mr. HARDWICH thought the time was come when they ought to have a better paper and a more certain method of preparing it than they had hitherto had. The new process of toning was now getting into universal use, and it was admitted that more difficulties existed than before. Complaints were made constantly by many persons that they could not get on with it. There was one point in Mr. Hughes' paper with which he was struck as being entirely opposed to his own experience. It was now some years since a committee was formed, in connection with the society, to examine into and report upon the question of printing. They had obtained samples of paper from various makers. He then made up his mind as to the characteristics of the various kinds; but he found some of these conclusions differed entirely from the experience of Mr. Hughes with the same papers, which led him to the opinion that the papers must have altered since that time. The papers which he had found soft Mr. Hughes had found hard. In his hands the English papers were hard and took a high gloss; Mr. Hughes found them soft and absorbent. He thought that the cause would be best served by a thorough examination into the question of sizing; so as to know on what the production of a uniform and satisfactory paper depended. As to the method of toning, he had examined the alkaline process with great care, and found in it many elements of security. The point required was, therefore, a suitable paper; for it was certain that minute changes in the quality and preparation of the paper would effect the results by this process more than by the old one. He did not despair of overcoming the difficulties by a proper examination, and he thought the right direction for present examination was an enquiry into the influence of sizing. At present we did not know much on the subject; we knew that one class of papers was sized with gelatine and another with starch. But two papers both sized with starch would give very different results. Various manufacturers had, doubtless, each their own method not known to others. He thought the paper required was a starch sized paper—some samples of the *Rive* paper appearing to meet all their wants; but the difficulty was to ensure uniformity. A gentleman called on him at King's College, about eighteen months ago, with a paper said to be made in this country. With this he had made a number of experiments and was nearly satisfied. It gave nice tones, and was free from mealiness, and the other deficiences alluded to. He did not know whether this could be produced uniformly as good; but since then he had got none so good. If he rightly understood the matter, the name *Rive* did not necessarily imply either one maker or one quality.

The CHAIRMAN asked if the composition of the original pulp were not as important as the sizing.

Mr. HARDWICH said that was doubtless an important question;

but the sizing was, he thought, more so. Some of the paper which gave satisfactory results, he had found on testing, was decidedly acid, and he had since tried the addition both of acetic acid and citric acid to the albumen. Of the latter he had added two grains to each egg. It had the effect of making the albumen very thin and limpid, so that it ran through filtering paper nearly as freely as water, but still gave a good gloss to the paper. A general impression was that the thinner the albumen was, the less gloss it would give; but in this case the contrary was the fact. It was thought by some that the addition of such substances as gum would, by making the albumen thicker, give more gloss to the paper. The truth was, they caused less gloss. There was no doubt then that the addition of acid made the application to the paper easier without interfering with gloss. It had, however, somewhat interfered with toning; the paper with which he was then working was one which, even without albumen, did not tone readily. He thought if a plain paper which toned readily, were coated with albumen, which had had citric acid added, probably both difficulties would be met. One of the greatest difficulties in the case was the fact that photographers were entirely in the hands of makers of paper, and they probably did not quite know what was required. He trusted the subject would now be thoroughly investigated.

Mr. Malone said, that one difficulty arose out of the fact, that large makers did not think it worth while to step out of their regular course of business, in order to make experiments for photographers, and that English makers were not in the habit of making the same paper as the continental makers. Again, the secrets of sizing were not generally disclosed, and we did not know, therefore, many of the points which materially affected the question. At times our own makers failed to size their papers to their own satisfaction, from decomposition taking place in the size, and the same might occur in continental papers, and thus affect uniformity of result. If the resinous soap used by French manufacturers became decomposed, and the resinous matter was liberated partly on the surface, that would produce an irregularity in albumenizing, as these parts would resist the albumen, whilst others would absorb it. This might be one cause of want of uniformity. He thought it might be well to treat a paper with a weak alkaline solution to alter the condition of surface, and then try if albumen would take better and give better results. Unless they could by some means get rid of the necessity of trusting to others, they could have no security at all. He hoped the society would put forth all its influence to induce some maker with adequate machinery to take the matter in hand, or perhaps they would have to endeavour to form some kind of joint-stock company for the purpose. Regarding the difficulties of preparing the paper he thought many of them arose from not following some one good method. He believed it was at times customary to use the albumen in a state of putrefaction. It should be known that, under these circumstances, sulphur and phosphorus were liberated, and injurious results produced. He thought that the wilful preparation of paper in this way amounted to something like fraudulent adulteration. As to the question of silver, although where rapid printing were required, 100 grains might be used, he thought if the silver were pure, sixty grains would give good results, and be found a more profitable strength than the former. If the nitrate were dissolved and evaporated more than once, and then heated barely to fusion, so that the whole of the nitric acid were expelled, it might then be used at once. As to the toning, he was not going to defend the old method, but still he thought Mr. Hughes' very doleful picture was a little overdrawn or exaggerated, and that it was scarcely philosophical thus to overstate the case. It must not be overlooked that some of the pictures toned by the old process did remain permanent. It was not, moreover, quite clear, that gold itself was unattackable by sulphur compounds, indeed, it was known that sulphide of ammonium would decompose gold, and as we could not exclude our prints entirely from the action of sulphur we were not quite certain even of the permanency of gold-toned prints. So long also as some of the earliest photographs remained unchanged, it was clear there was something more in the subject than our philosophy had explained.

The Chairman: You think that the devil is not quite so black as he has been painted.

Mr. Malone: Precisely.

Mr. Shadbolt feared he would be in a minority in his opinion, as he preferred the gelatine sized papers to those sized with starch. He had a perfect recollection that when the printing committee examined this subject, they came to the conclusion that Hollingsworth's paper was one which gave the best results, both with gold toning and sulphur toning. That English paper was more difficult to manipulate he would admit; it was more difficult to albumenize, and more difficult to manipulate after albumenizing, on account of its tendency to curl up; but still he thought few photographers would object to a little trouble in securing good results. There was another point; much had been said about the advantage of mixing a little free acid with the albumen. From experiments made years ago his convictions were in the opposite direction, and he preferred to mix a little ammonia with the albumen, which made it more fluid and prevented it running in streaks; and the only care it required, was, that it should be dried at once before a brisk fire. There was another point he would mention. Some time back a paper was read before the Manchester Society, by Mr. Mabley, who noticed the fact that by using a little free nitric acid in the nitrate bath, the prints received the toning action more readily, an observation in which he was corroborated by other members at the time.

Mr. H. G. Bohn said he had not known before that so much difficulty existed in connection with this subject of paper, and he now thought there where men who would make experiments for them; and would supply them with a paper from pure linen rags. This paper he thought if sized with pure vellum size, would probably answer their purpose. It would probably be double the price now paid, but that he thought would not matter. There were three houses he thought who could make them a suitable paper; he would not name them there, it might be invidious, but would be happy to tell any of the gentlemen privately.

A conversation on this subject ensued, in which the Chairman, Mr. Hardwich, Mr. Shadbolt, and Mr. Bohn, the latter gentleman remarking that none of the French papers were from pure rags, but commonly contained as much as 25 per cent. of wood, a substance he conceived scarcely likely to suit the purposes of the photographer.

Mr. Sebastian Davis wished to make one or two remarks on testing the nitrate of silver bath. Mr. Hughes had referred to the hydrometer, and although in another paper he had given an interesting account of experiments with this and other testers, he (Mr. Davis) must remark that the hydrometer was scarcely a philosophical test for such a purpose, because of the accumulation of nitrates of soda, ammonium, &c., which must occur in the nitrate bath, adding to its specific gravity and disturbing the conditions in which the hydrometer afforded any idea of the amount of silver in the bath. It was a very simple and efficient method to use the ordinary minim measure, which would serve without any other specific instrument. As the equivalent number of nitrate of silver was 170 ($Ag\ 108\ N_{14}\ O_{48} = Ag\ NO_6$), and that of chloride of sodium 58·5 ($Cl\ 35{\cdot}5\ Na\ 23$), it followed that ·344 grains of the latter would convert 1 grain of nitrate of silver into a chloride. If, therefore, we dissolved 88 grains of anhydrous chloride of sodium in one pint (16 ounces avoirdupois) of pure water, we should obtain a test solution, each half drachm or 30 minims of which, measured in the ordinary minim glass, would convert one grain of nitrate of silver into the metallic chloride.

Mr. Thomas said he had heard of many of the difficulties of toning albumenized paper, but had never met with them himself; probably because he was very careful. He preferred the Saxo paper, as giving an agreeable colour, but it should be carefully selected of good quality. He used nearly pure albumen, and was careful to have the room in which the albumenizing was conducted at a sufficiently high temperature to dry the paper rapidly.

Mr. Hardwich asked Mr. Thomas if he had ever tried the use of acid.

Mr. Thomas had never used it, as he got on very well without it.

Mr. Shadbolt asked Mr. Thomas, if he would describe what he meant by an agreeable colour.

Mr. Thomas said it was somewhat difficult to describe, but he might refer to Mr. Bedford's pictures in the present Exhibition, as illustrations of what he meant.

Mr. Sutton said perhaps some specimens of stereographs which he laid on the table would afford illustrations of the tone meant.

After some further conversation the discussion was adjourned until the March meeting, and the proceedings terminated.

Newcastle-on-Tyne and North of England Photographic Society.

We recently announced the formation of a photographic society in Newcastle-on-Tyne. The new society is now fairly organized, and gives high promise of activity and success. The officers for the current year are as follows:—

President—The Right Hon. T. E. Headlam, M.P.

Vice-President—G. C. Warren.

Honorary Secretary and Treasurer—Joseph Fraser McKie.

Council—P. M. Laws, W. H. North, R. Porteus, R. S. Hill, Robt. Anderson.

The first general meeting was held at 28, New Bridge Street, on Friday evening, Mr. George Christopher Warren, one of the vice-presidents, in the chair. Mr. Joseph Fraser McKie, Hon. Sec. read a detailed account of the organization and establishment of the society, also its constitution, and list of officers for the present year, which elicited the hearty plaudits of all present. The Chairman read a paper entitled, "Photography as it is." He remarked that—

This being the first paper read before the society, he did not propose to bring before them any new process, but rather to give an account of the present state of the art, and show that photography was not confined to mere portraiture or depicting of landscape scenery; he also stated that the art had reached such a degree of importance that no less than four journals were now devoted solely to disseminating photographic information. Numerous societies now exist, and are instrumental in bringing forward improvements in the various processes of the art, and in bringing to bear the knowledge and experience of many of the most noted scientific men of the day, in their several vocations. The various societies have obtained the patronage of men of rank and fortune. At the meeting of these societies we find discussed every subject connected with the art, comprising chemistry, optics, mechanics, &c. &c. Mention was made of the various modifications made in the several processes during the last few years, particularly with respect to the various dry methods lately introduced. In speaking of the improvements in the optical department, special mention was made of a new lens invented by Mr. Sutton, whereby a picture embracing a much larger angle of view than the ordinary view lens is capable of producing, can be taken. Reference was then made to the various new printing processes for insuring permanency and stability, the present mode of printing with silver salts being by every honest photographer considered unsatisfactory. This part of the paper was illustrated by specimens of various kinds of photographic carbon printing and engraving. Reference was made to the application of photograpy to wood engraving, lithography, &c., and special notice was made a patent process for obtaining photographs on glass and ceramic ware, requiring to be burnt in a furnace for the purpose of fixing. A specimen of this process was introduced. Amongst other applications mention was made of its use in astronomical observations for registering the variations of the thermometer, barometer, and magnetic needle. It was also useful to the architect, the engineer, the microscopist, the military profession, &c. It was also stated that photography was being used in the Ordnance Office at Southampton for reducing the ordnance surveys, and that by the use of the art for this purpose, a saving to the country of £30,000 will be effected. Towards the conclusion of the paper, reference was made to the influence of the art on the artistic taste of the public. He glanced at several useful applications of photography, showing that it is by no means confined to portraiture, but that its sphere of usefulness is very large. In conclusion, he said, if each member gave an occasional paper, or statement of either failures or successes in any branch of the art, or even put a few questions as to the why and wherefore of anything connected with it, he had no doubt they would always be able to pass off a pleasant, instructive, and amusing evening.

At the close of the paper an animated conversation took place, which lasted some time. The rest of the evening was spent in examining some fine large photographs kindly supplied by Messrs. Laws, North, and Warren. Mr. Laws presented two proofs of his very beautiful views of the Ruins of Tynemouth Priory, for the portfolio of the society. A vote of thanks was given to Mr. Laws. The thanks of the meeting was also given to Mr. Warren for his excellent and interesting paper. The next meeting will be held on the first Friday in March.

Photographic Notes and Queries.

Magic Lanterns.

Sir,—As many of your readers are at the present time interested in *magic lanterns*, it may benefit some of them if they will refer to Nos. 84, 87, 88, 89, 90, where they will find some little correspondence on the subject. If not occupying too much of your space, I should like to repeat a hint then given, viz.: to form an exchange club of transparencies suitably mounted for the *magic lantern*, on the principle of the Stereoscopic Exchange Club. If any of your readers think the *idea* worth carrying out, I shall be most happy to render any assistance in my power; for this purpose I enclose my address.—And remain, yours very respectfully, F. R.

[We shall have pleasure in aiding our readers to form an Exchange Club for the purpose indicated.—Ed.]

Hints to Operators.

THE HYDROMETER BATH-TESTER.

Mr. J. C. Leake, jun., whose inventive ingenuity has given several clever contrivances to the photographic world, sends us the following:—

I fully agree with the remarks made by Mr. Hughes, at a recent meeting of the North London Society, on the use of the hydrometer test for the silver solutions used for sensitizing paper, having myself made use of the principle for five or six years with complete success.

The instrument I use, however, is not a regularly manufactured hydrometer, but a home-made one, which, with the method of making, I will, with your permission, describe.

Take an ordinary test-tube, about four inches long and half an inch diameter, and glue into it a slip of paper having a line drawn across it, about an inch from the top, or open end of the tube. A cork must now be fitted into this, and, having procured some very small shot, and some solution of the strength required for printing, say sixty-five grains, in which to float the tube, drop the shot into the test-tube till the line is brought to a level with the solution, of course allowing for the weight of the cork. If this be carefully done a very accurate instrument will result. To use it proceed as follows:—Pour into a suitable vessel the solution to be tested, and, if it be found too weak, add a 120-grain solution till the requisite density is obtained, and the mark is again level with the surface of the solution.

Of course if a little time be spent in graduating the tube in the first instance, the number of grains deficient per ounce can be ascertained; but I have found the first-named plan sufficient for all practical purposes.

Hoping this may prove useful to those, who living at a distance from town, may not be able to procure the usual form of hydrometer,—I remain, &c. J. C. Leake, jun.

[Mr. Leake has handed us a bath-tester made on the principle he has described, which for general practical purposes, will, we doubt not, answer exceedingly well. The one before us is weighted with mercury; but we imagine that the small shot suggested will, in the hands of amateur mechanics, answer better, as it is difficult to cork down mercury, so that it will not escape in minute globules when the tester is laid down. The method of making the test-tubes, referred to by Mr. Leake, is described at page 77 of the Photographic News, vol. iii, in the series of articles "Amateur Mechanic." As the home-made instrument is only recommended to those who have not ready facilities for procuring a properly graduated meter, the means of making the test-tube may be desirable. We trust that, for printing purposes, many of our readers who have neglected the testing of their solutions hitherto, will, when the means are so simple, avail themselves of its advantages.—Ed.]

A Correspondent says:—In order to show how fully I appreciate the Photographic News, I take this opportunity of acquainting you, that I am now very busy recording in my note-book such recipes, &c., as have been, from time to time, given in your work, and which will be most useful to me in my future career; and by continuing my entries therein, as each number of the News issues from the press it will form a valuable reference book, in which I hope to be able to insert anything of interest that may hereafter come within my own observation.

Many of our readers would find this practice of great value, for the double purpose of forming a useful book of reference, and fixing the subject in the memory.

Talk in the Studio.

PHOTOGRAPHY AT ST. PETERSBURG. H. Denier, a very celebrated Russian Photographer, bids fair to shoot a head of all we have yet produced in the way of photographic portraiture. We saw recently a large group of eight, from a plate about 18 by 14, each figure in focus, perfect in half tone, and without signs of distortion. The grouping was easy, natural, and graceful; nothing of artistic effect being sacrificed to the generally limted powers of the lens, which in this case appeared to meet the demands made upon it.

COPYRIGHT IN WORKS OF FINE ART.—The Attorney-General gave notice in the House of Commons, on Tuesday evening, that he would move, on Friday the 15th, for leave to bring in a Bill to amend the law of copyright in works of fine art. We trust that photographs will find recognition in the new Bill.

DISPUTED COPYRIGHT.—A case of considerable interest to photographers will be heard at Guildhall on the 13th. The action is for infringement of copyright in an engraving, by the sale of photographic copies. Mr. Shew is the defendant.

PHOTOGRAPHIC COLOURISTS' CLUB.—Messrs. A. H. Wall of 28, Old Bond Street, and Walter Petty, of 121, Regent Street, are now engaged in organising a club of photographic colourists, one of the chief objects of which will be of professional utility and importance. Communications will be gladly received by the above gentlemen.

ROYAL ACADEMY OF ARTS.—Mr. P. F. Poole has just been elected Academician in the room of the late A. G. Chalon. Richard Ausdell, Thomas Faed, Edward M. Barry, and Baron Marochetti, were elected Associates.

NEW DRY PROCESS.—In the new edition of "Mr. Harwich's Photographic Chemistry," a new dry process will form an interesting feature. Tannin plays an important part in the preservative, and we hear excellent accounts of the certian and beautiful results of the new process.

A NEW METHOD OF COLOURING PHOTOGRAPHS has been discovered by Professor Seibertez, a painter of Munich. He uses the colours in a dry state, and fixes them by the water-glass.

SILVER ORE.—A new method of extracting silver from the ore, said to have been suggested by the photographic process of fixing, with which it is identical in principle, has recently been introduced by Herr von Pakera, an Austrian chemist, and is exciting considerable attention. The silver ore is first roasted with green vitriol and common salt, so as to produce chloride of silver. This is dissolved by means of hyposulphite of soda, and sulphide sodium is then used to precipitate the precious metal as sulphide of silver. This, on being heated, allows tho sulphur to escape as vapour, and the silver is left pure.

PHOTOGRAPHIC CHEMICALS IN RURAL DISTRICTS.—*The Chemist and Druggist*, a monthly circular, issued only to "the trade," in alleging its reasons for supplying a brief description of the Photographic Chemicals which should be found in the stock of every village chemist, thus facetiously describes the position of the dispenser of drugs in the rural districts:—Photography has spread so wonderfully through the length and breadth of the land, that there is scarcely a hamlet or village too small or insignificant not to be visited at least occasionally by some of the votaries of the art. The quiet chemists of the picturesque townlets are now and then frightened from their propriety by the apparition of a mild gentleman in spectacles, with very black fingers and wristbands, who asks, in a very courteous, but excited manner, for a small quantity of pyrogallic acid, he having "unfortunately left his bottle behind him"—or, if there is no artistic "bit" in the neighbourhood, the questioner is very possibly a mountebank-looking party, in a velveteen coat, with no shirt collar, a closely shaven beard, and curly black hair, who asks for "two hounces of postif clodion, nooly mixed." The poor chemist is aghast, he looks furtively in his Pharm. Lond. for 1833 for pyrogallic acid, and finds nothing but gallic acid, which the mild gentleman politely tells him will not do. As for the "postiv clodion," he supposes the man must mean collodion, and forthwith serves him with two ounces of it, in a fine ropy condition, which is shortly afterwards returned by the seedy "professional," with a few observations not remarkable for their elegance, or their friendliness to the chemist's eyes. The poor amateur is obliged to go away disappointed of his view, and the "professional" is prevented from taking a number of patent enamelled American ivory-type portraits of the Chloes and Strephons of the place, at 6d. each, frame and glass included.

To Correspondents.

INSENSITIVE.—The nitrate bath will dissolve off the albumen from two causes, either being very weak or very alkaline, or both. The repeated use of kaolin tends to produce alkalinity. See Mr. Hughes's article on "Bath Testers," and make up the solution to a full strength.

CAPT. BELL.—You will find formulæ for toning in the ALMANAC, which give excellent results.

W. H. WARNER.—We will have pleasure in proposing you as a member. Mr. Howard's address is 12, Whittingham Villas, Studley Road, Stockwell.

W. W. M.—Your 9in. plano-convex lens may be used with artificial light, on the same principle exactly as the condenser in Woodward's camera. See article in our next number.

M. M. D.—We believe the Hydrometer Tester is kept by dealers generally. As Mr. Hughes advocates its use he is bound in consistency to keep it, and we believe you can procure it from him. See Mr. Leake's communication in the present number.

SEASIDE.—The Photographic Exhibition generally closes towards the end of March.

N.—Your communication is interesting, and we will give it further attention. Distilled water may sometimes contain a minute portion of organic matter if kept long in a vessel of wood, &c. It would not necessarily affect the nitrate of silver except on exposure to light. The addition of a bromide will generally partially restore the sensitiveness of an old insensitive iodized collodion. [This answer was in type last week, but was omitted through press of matter. We are always glad to receive your interesting communications.]

J. N.—1. The back lens of the Triplet can be used as an ordinary view lens, and covers a field about one-fourth larger than the whole combination. 2. The lens referred to in the description you mention appears in all respects similar to Mr. Dallmeyer's stereo lens, with the exception that in the latter the back lenses are 2½ inches in diameter, and those described, 2¾ inches. The back lenses are not cemented. The front and back lenses in the description to which you refer appear to be a little nearer together than in Mr. Dallmeyer's, in which the same result—lengthening the focus, and consequent larger field—is obtained by making the back lens larger. We have already stated our opinion of one we have had in use about six months. The literals to which you refer are very provoking to us. The hurry attending the final revision is the only plea in mitigation.

JUVENIS.—We prefer in portraiture to focus for the eyes, using the full aperture, and then insert such a stop as the light will permit afterwards. In landscape for the most important object. Where the light will permit it is as well to focus with the stop *in situ*; but sometimes this is difficult, and the stop must be inserted afterwards.

PROTOSOL.—See the papers of Mr. Warren De la Rue and Mr. Fry on "Celestial Photography" in the present and last volume of the PHOTOGRAPHIC NEWS, and an article on the "Photoheliograph," in last volume. Another article on the subject will probably appear shortly. With your camera extended about 12 inches beyond the eye-piece, you should get an image about 3 inches diameter.

W. D.—Fenton's view of Furness Abbey, No. 22, in the Photographic Exhibition, is also exhibited in the Architectural Photographic Exhibition; and the number, so far as our memory serves us, is 211. 2. Leake's tent usual size, is scarcely large enough to manipulate plates 12 by 10; but we believe larger sizes are made. 3. The new triplet decidedly. The other lens you name gives serious curvature of lines; the triplet quite straight lines. Two negative lenses are now supplied with the latter: one for copying purposes giving a perfectly flat field; and one for landscape work with a little rounder field. For architectural views, chiefly on one plane, use the copying combination; for others, the latter combination. We like Kinnear's camera; but care is required to fix it so that the lens and ground glass are quite parallel.

JIMBY.—The fault is in your paper. See Mr. Hughes' article, and the discussion at the Photographic Society in present number. Use your toning bath a little more dilute, so as to tone more slowly.

THOS. W. B. COOK.—The best plan is either to use a number of dark slides to contain a sufficient number of plates, or to use a transferring box for changing the plates. Such boxes are made, we believe, by camera-makers generally; we have seen them at Mr. Meagher's establishment. We shall have pleasure in introducing you. The subscription is half a guinea.

T. M. G. has succeeded very well with the hot-water process, with the exception of being troubled with small round transparent spots. Can any of our readers help him?

J. B. ROBINSON is thanked for his communication.

A SUBSCRIBER FROM THE FIRST.—Your scrolls will not stand damp without some varnish; but we do not remember any varnish that will be sufficiently transparent and at the same time without gloss. Almost any varnish will do, but a soft one such as mastic will be least liable to crack. The addition of a little white wax will prevent excessive gloss.

W. L. C.—Salt or chloride of sodium will not precipitate silver from a solution containing cyanide of potassium, as cyanide dissolves chloride of silver. The plan given in our last, is the best for a mixture of all residues. The spongy mass or globules may be fused into one lump, but it is not necessary, either for sale or for convertion into nitrate.

X.—We will enquire.

LEO. DAFT is thanked.

F. RICHARDS.—We will communicate by post.

F. G. G.—Use nitric acid to your positive bath. The amount will depend somewhat on the strength of the bath. If you add too much, the sensitiveness will be diminished. If your bath have 35 grains of silver to the ounce, about half a drop of nitric acid may be added to each ounce of solution. Add a little less at first, and then try a plate.

Several correspondents, whose letters arrived late, and Mr. Lane's communication in our next.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 PATERNOSTER Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. THOMAS PIPER, at the Money-Order Office, St. Martin's-le-Grand.

THE PHOTOGRAPHIC NEWS.

VOL. V. No. 128.—*February* 15, 1861.

THE PHOTOGRAPHIC SOCIETY OF LONDON.

THE Report of the Council, and the Financial Statement of the Photographic Society will be found in another column. Neither of these documents are suggestive of very pleasant contemplations, nor can we congratulate the society—nor photographers at large, as interested in its stability and progress—on the results of the year as indicated in these documents. Unwilling, however, as we are to enter into the subject, there are one or two points connected therewith, bearing on subjects of general interest, that call for brief observation.

A word in passing is due on the unseemly altercation which arose at the annual meeting on Tuesday week. As our readers will see on reference to the report of the meeting, published in our last, that when the report was read, the chairman invited comment or questions upon it from the members. We presume that by this comment was meant eulogy, for the moment that Mr. Malone began to question the truth or propriety of some of its statements, he was met with the most energetic interposition of the chairman, who distinctly told him he would not permit such observations to be made.

Mr. Malone's protest against the report, we conceive, to be a most legitimate one. Amongst the events of the year, forming, with the greatest propriety, a subject of allusion, and an occasion of graceful eulogy, was the death of the late Mr. Peter Fry, one of the earliest members and chief promoters of the society. But that in passing a just tribute to the dead, opportunity should have been siezed in the report of a scientific society to offer a direct and most uncalled-for affront to a living gentleman, and one to whose researches the art and science is perhaps more indebted than to any other man alive, is a circumstance that we must confess we cannot reconcile with our ideas of propriety and decency. We are not about to seek up or uncover old sores, nor to enter into the slightest discussion of the claims of Mr. Fox Talbot. The subject was long since dead and buried, and it might reasonably have been hoped that all the rancour and heartburnings arising out of it had been entombed with it. We cannot but regret the singularly warped ideas of propriety which could induce the Council, in referring to the departed gentleman, to occupy a large portion of the report in connecting his name with some of the most painful events in the history of the science he loved, and endeavour to make him, from his ashes, subservient to the purpose of branding a stigma on a name so illustriously connected with the most important discoveries in that science.

Mr. Malone, we repeat, was not only in order, but, connected as he was with the proceedings referred to, and holding the opinions he was known to hold on the subject, he was bound in common honesty to himself, and those with whom he had been associated, to enter his protest against these clauses of the report. The attempt, under such circumstances, to silence him by the use of a musty Latin proverb, and by stigmatising the good taste of his protest, was most unjustifiable. If correct taste decide that nothing but good shall be spoken of the dead, it should likewise decide that the same immunity should be extended to the absent, and we think also it should decide, *à fortiori*, that the dead be made not a shield from behind which to stab the living. Mr. Malone might, therefore, with great propriety, have flung back the charges of bad taste; and we think if he had moved an amendment to the effect that the paragraphs referring to Mr. Fox Talbot be struck out of the report, he would have carried the sympathies, if not the voices, of a large portion of the meeting. In one point the propriety of his protest lies already acknowledged by the Council, for it will be observed, on referring to the published report, that the terms to which Mr. Malone took especial exception when it was read, are now expunged from the paragraph referring to that subject.

We must repeat that in making these remarks we do not revive the question of Mr. Talbot's rights, nor in any sort either affirm or deny them. The subject is a wide one, involving many considerations, and admitting of much argument on both sides. It affects no interests now—let it rest in peace.

Another startling feature of the report, or rather of the financial statement, is the fact that there is during the year an excess of expenditure over income of between three and four hundred pounds. During the last few weeks there have appeared in our pages letters from various correspondents, urging the necessity for some reform in the constitution or management of the society. We are by no means necessarily identified at any time with the opinions of our correspondents. Occupying an independent position, and not the organ of any society, or section of photographers, our columns are at all times open to temperate and intelligent discussion on all questions bearing upon the interests of the art or its votaries. We do not necessarily endorse all the opinions of these correspondents, therefore, when we point to this one startling fact, as corroborating, in a forcible manner, the importance of this call for reform; we may add that this call does not simply emanate from the few correspondents whose letters have been published, but finds an echo in private letters we have received from many of the most eminent provincial artists and members of the society, and in the conversations we have had with gentlemen occupying the very highest position in connection with the art in the metropolis.

We should regard it as a very heavy blow and great discouragement to the art generally, and as a circumstance, the depressing influence of which can scarcely be at present estimated, if the Photographic Society of London — of England we may say—were to cease to exist. Nothing else which could arise in its place could possess the same prestige, or exercise the same influence. To repeat the remarks of "Progress," "No society can be compared with ours for the advantages it possesses. It is the oldest, the largest, and the parent of all others. It is patronised by royalty, graced by nobility, and made illustrious by distinguished members. It established the first journal exclusively devoted to our art, and by its successive, annual exhibitions gave that impetus to photography that has made it what it is. And shall a society like this die out, when small provincial and suburban societies are full of life? Nothing is wanting but skill and energy to make this Society greater than ever it was." We fully endorse these remarks, and yield to no man in a desire to see this greater prosperity. But if this deficit in the material sources of prosperity occur many years in succession it does not require a prophet to foretell the result. We do not here enter into any examination of the causes of this excess of expenditure over income, and we are aware that now is not the time for specific steps of any kind as affecting the constitution or goverment of the Society; but it is while facts of this kind are fresh that a public opinion may be created, which, by its pressure from without, may exercise an influence which may save the Society from that atrophy to which it seems in danger of falling a victim.

In concluding, it is unnecessary that we should do more than briefly refer to some comments in the columns of a contemporary on the first letter of "Progress," which is regarded as an "anonymous attack," or a "stab in the dark." If it were necessary to seek for an answer to our contemporary's defence of the Society, we could very easily select from his own pages strictures infinitely more denunciatory of the proceedings of the Society than anything in the letter of "Progress." The simplest answer is found, however, in the article which this letter has drawn from our contemporary. He says "the meetings of the Society are always interesting *when* the best men take the trouble to attend." This very introduction of the conditional mood implies perfect coincidence with the views of "Progress," who complains that they *do not* attend. Our contemporary then proceeds in detail to state how "first-rate men have been kept in the background," and further, what "ought to have been done," &c., &c., in all of which he confirms, so far as he goes, the views put forward by "Progress."

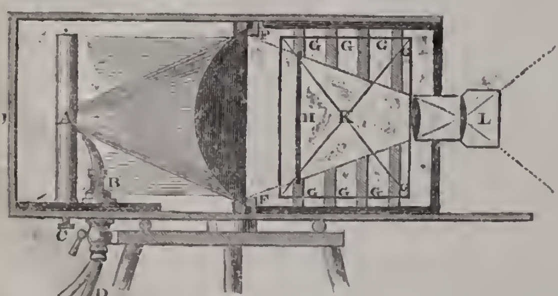
In regard to the question of anonymous writing on such a subject, the canons which should govern such matters perhaps are not very well understood, but to every honest journalist they should be as clear as we think they are simple. Anonymous comment on matters of public interest so far from being un-English, as our contemporary asserts, is pre-eminently an English practice, and is carried out almost universally, not only in English journalism, from the *Times* downwards, but in what is considered the highest order of periodical and critical literature, the various Quarterly Reviews. Where comments are made on any matter of public interest, if those comments are just and true, they need not the aid of a name or personality to give them weight. If they are fallacious or dishonest, they would gain nothing from the endorsement of any personality. Where private interests of any kind are affected, whether they concern a man's good name, or his trade wares, then we agree with our contemporary that anonymous attacks are altogether unjustifiable, and the insertion of them would be most reprehensible. If an individual be attacked, his assailant is a coward if he wish to fight under a mask. To such assassination our columns shall never be open.

The letter of "Progress," whom we know to be one of the oldest and staunchest friends of the Society, was in no sense a "stab," still less a "stab in the dark." Our esteemed contemporary, the Editor of the *Notes*, has here scarcely combined his customary clear vision with his refreshing plain speaking.

THE LIME LIGHT:

Its Application to the Solar Camera.

The annexed sketch shows the method in which the lime light may be adapted to the solar camera.



The bottom of the camera is partly cut away to allow of the lime-light lamp being slipped into it without removing the stopcocks.

The bottom of the lamp is shown by a black line.

A is the lime light, which may have one or more jets attached to it, or several lamps may be fitted in a line with each other; B, the blowpipe: C, the screw for occasionally raising the lime so as to present a fresh surface to the action of the gases. This screw may be made to fit so nicely as not to interfere with the steadiness of the camera during adjustment; D shows the position of the stopcocks and supply pipes; E the condenser which fits against a wooden bed, and is retained in its position by the wooden clamps F F, which turn on the screws or pivots by which they are fixed upon the bed of the lens. G G G G are the separate sized holders for the negative about to be copied, which slides into them in grooves made for that purpose. They are fixed to that part of the camera holding the portrait lens as shown by a black line reaching up to the nuts F F. This part of the camera is made to slide out bodily to enable the operator to place the lime light on this side the condenser, if he wants to use the light in parallel rays for printing, &c., &c. The bottom of this part of the camera will also have to be partly cut away to allow the admission of the stopcocks. It is extended for the purpose of allowing the lamp to be placed in the focus of the light, the distance of which from the condenser is exaggerated in the drawing the more plainly to show the principle of the whole arrangement. This sliding portion of the camera will also have to be partly cut away on that side which is next to a door shown by diagonal lines intersecting each other at K. Another door is hung at the back of the camera at J, for the admission of the lamp. In this door is a strip of dark *purple* or blue glass, sufficiently broad to enable the operator to see to adjust his lights to the greatest degree of brilliancy and *whiteness*. This is easily done after a few trials by observing the reflection of the flame upon the condenser. The inner part of this chamber may be lined with tin and should have a kind of magic-lantern chimney to carry off any unnecessary degree of heat which is sure to be created in so small a space.

The whole arrangement may be placed on a table, or on four legs of its own, or on a tripod stand as desired.

S. S. B.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Antiquities.—This word explains its meaning. The time is passing away in which the antiquary was regarded as an idle and eccentric personage, delighting in musty old records, and dusty old relics—a very harmless, useless, and peculiar specimen of humanity, and a capital butt for ridicule. The final exit of such a stupid, shallow-pated time must be hastened by photography; the art which brings to every home these long-enduring, but fast-decaying, witnesses of ancient and modern history, witnesses which, uninfluenced by imagination or prejudice, illustrate wonderfully the most interesting of historical facts, verify dates, correct errors, detect imposition, explain mysteries, and recreate in living reality those dim periods of the past which, to every thoughtful mind, have such intense interest and high importance. The antiquities of his country must possess a rare charm for every patriotic man who can exclaim in the language of rare old Spenser—

> "Dear Country! Oh! how dearly dear
> Ought thy remembrance and perpetual band
> Be to thy foster child, that from thy hand
> Did common breath and nouriture receive!"

It is often a subject of regret with me that in this important and interesting branch of our art we have, in comparison with its value, so few workers. How many fine antiquities and monuments, now never seen save by the privileged few, are still to be reproduced by photography and made public, to the enlightment and improvement of both the casual reader and the earnest student. Truly photography has yet to be properly appreciated in all the wondrous diversity of its applications. Antiquities, in an artistic sense, will, of course, refer purely to relics of ancient art; but I thought it well to point out briefly the importance of the word in its more extended sense in connection with photography.

Anatomy.—Photographers who emulate such ambitious aims as the works of Lake Price and Rejlander frequently display, should certainly possess some knowledge of this branch of art. Muscular action is the painter's chief vehicle for the display of every predominant passion and ruling emotion of the mind; and it is to his anatomical knowledge that he looks for the proper expression, rather than to the mimic powers of his model. It is seldom, indeed, that the actor can, by the mere effort of his will, bring into play all the muscles which by their action indicate certain conditions of the mind; but when that actor's feelings are wrought up to the desired pitch, then, without a thought, without the slightest desire for securing any outward sign, every active muscle becomes full of forcible expression, and the passion speaks out from every part of the model's exposed frame. To recognise the various combinations and different degrees of intensity of the passions as expressed by muscular action, in order to reproduce them in his productions with due force and truth, it is evidently necessary that the photographic artist should understand that portion of this science which is generally studied in connection with pictorial art. Save in cases of an accidental or extraordinary character, it is no use telling your model to look as if he felt this or that; and it is not always that you can so work upon an *ordinary model's* mind as to bring certain muscles *instinctively* into play; but when you understand how and to what extent muscles act under a certain influence, the model may be educated with more success than is commonly believed to express outwardly the inward emotions and passions of our nature. That this could be accomplished I did not myself believe, until the works of Rejlander converted me; for from *some* of his models he has secured that force and effect of muscular expression which few painters have equalled, and none surpassed. I have not now the necessary time or space at my command, or I would here give a few rules for those who are ambitious of excelling in anatomical expression. "Le Brun's Passions" is a good work on the subject, notwithstanding many faults; although I do not think invariable rules can or ought to be laid down for the government of expressions subject to so many influences. A good and useful work might be written upon this branch of photographic art, but its practitioners are so few, and their efforts so partially appreciated, that such would not now perhaps meet with the encouragement it would deserve. Many will, perhaps, even condemn these one or two meagre hints, as calculated to lead the ambitious astray; but let such only look over a folio of Rejlander's picture photographs, and if they do not bring them to another way of thinking, I am no conjurer, nor they unprejudiced observers.

Arrangement.—Artistic arrangement comprises composition, chiaroscuro, symmetry, and almost all other qualities which give picturesque value to an art production. In the arrangement of light and shade, different eminent masters have adopted different methods, but they all tend to a similar result, viz. breadth of effect. Some endeavour to get their general mass of shade of a wedge-like form, the base being at the side of the picture and the apex near the horizon; such an effect is commonly found in the works of Stanfield, Collins, and others. Some have treated the mass of *light* in precisely the same way, and obtained very excellent effects. A few of Rembrandt's paintings are so treated. The general mass of light or shade may take any form, providing it be agreeable and in keeping with the sentiment of your picture. The relative proportions of light and shade are of course dependent upon the general effect desired. The most common arrangement of lights and darks is to be found in the old principle of three lights so placed as never to indicate a straight line in any direction, varying in shape and degree of brilliancy, and forming, if connected by lines, an unequal triangle. This principle may be seen skilfully carried out in most of our modern masters' pictures. It is somewhat complex, and not always within a photographer's grasp, unless it be in portraiture, when the head at once forms the principal light, and the hands those which act as a base to the pyramid; when these three lights should receive the treatment above described. A favourite arrangement with Turner was that given by a dark tree, or similar object, reared against a luminous sky, and repeated by some dark spots near or in the foreground; these darks being connected by a mass of middle tint. I have seen a very similar effect in some of Wilson's glorious stereographs of sunsets. The relieving of a dark mass against the pictures' most brilliant light produces very powerful and picturesque effects *when well managed;* but the danger in unexperienced hands lies in the probability of a spotty and unpleasant effect resulting from the attempt. *Such arrangements must always be subject to the attainment of breadth,* without a proper knowledge of which your management of light, and shade, or chiaroscuro, will seldom chance to be artistic. Avoid getting the mass of light or dark in the centre of your view. In a well arranged picture, every line, whether it bound masses of light or dark, or indicate form only, must be considered in reference to the whole. Certain shapes, as indicated by lines, must be avoided, viz. such as are formal, too regular, or angular. Masses of mere light and shade should always be more or less indefinite in their forms. If your view embraces objects having many horizontal lines, take especial care to select such a point for your camera as does not make them appear parallel; either by throwing them into perspective, or picking out some spot which breaks them by an intervening object, or availing yourself of some other happy chance. Variety of form must be eagerly sought upon all occasions, for contrast is the parent of vigour. Never let the principal object in your view stand exactly in the middle of the picture; nothing looks uglier than a photograph of some one object so exactly dividing the space in which it is placed that you cannot help fancying the compasses were used to ascertain its exact position. This is a very common fault in photographic portraiture. When taking a street scene or avenue of any description, be careful that the point of sight to which the objects on either side converge do not fall exactly in the centre of the horizontal line. In such a selection, too, the light should not be so situated that both sides are equally illuminated. When any two objects of uniform appearance stand together, choose that point of view which will not render them at equal distances from any one other object; or from the sides, base, or top of your photograph's boundary lines; and choose that, also, which will give them with as much difference of shape and light or shade as it is possible to secure; uniformity being no friend to the picturesque. In a portrait of any kind, let the figure be a little to the right or left, never equidistant from the sides, and keep more space above and before, than behind or below it. This too is a rule of arrangement very commonly violated in photography. In photographing a single head it is often permissible to place it at equal distances from the sides, but then it must not be the same from the top and bottom. All these methods of arrangement must be consistent with *Keeping,** with *Variety,* with *Breadth,* and with *Contrast,* which latter is the parent of *Force* and *Brilliancy.* See also *Composition* and *Chiaroscuro.*

Artilise.—A capital word, which I think deserves retaining. We find it used in a remark of Montaigne's, who says, "If I were a philosopher, I would naturalise art instead of *artilising* nature." "The expression" wrote Bolingbroke, "is odd, but the sense good." To "naturalise art" is one of photography's missions.

* That is to say, you must not in aiming to carry them out destroy the consistency or truth of the whole.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analylsis.

Having in our previous chapters described the best methods of preparing nitrate of silver, we shall now proceed to the next subject on our programme, and consider its properties. In the crystalline state it forms transparent and colourless plates belonging to the right prismatic system. When heated to a temperature below redness it fuses readily without decomposition, forming a clear liquid which solidifies on cooling to a white, hard, fibrous mass. Its aqueous solution does not redden litmus paper, as is usual with the nitrates of the heavy metals, but, on the contrary, is said to have a slight alkaline reaction. It has a bitter, disagreeable, metallic taste, and acts as an acrid poison if taken internally. It destroys organic matter if exposed to the light. In 100 parts it contains 63·52 parts of metallic silver, 100 parts of metallic silver yielding 157·4 parts of nitrate of silver. It does not blacken in the air, or light, except when in contact with organic matter, or gaseous exhalations. Heated to redness it decomposes, yielding metallic silver and various gases. Thrown into red hot coals it detonates, and takes fire when mixed with powdered charcoal and struck with a hammer. Heated to fusion with zinc or copper it decomposes, but suffers no change if fused in perfectly clean iron vessels if no water is present. Placed in contact with copper, even in the dry state, it is reduced to metal, a change which also takes place if kept wrapped up in a paper for any length of time.

Nitrate of silver dissolves in one part of cold, and half a part of boiling water, the excess crystallising out on cooling. It dissolves also in four parts of boiling alcohol, the greater part, however, separating on cooling. It is insoluble in strong nitric acid, and is precipitated by that acid from its aqueous solution. It forms a crystalline salt with iodide of silver, and in strong solution dissolves considerable quantities of that and other insoluble silver salts.

From its aqueous solution iodide of potassium throws down all the silver in the form of an iodide, which is very sparingly soluble in excess of iodide of potassium, and almost insoluble in nitric acid or ammonia, which latter, however, turns it white. When the silver solution is so dilute that one part only is contained in 30,000 parts of water, this reaction ceases. When the iodide is dissolved in 500 parts of water, it gives a yellow precipitate with nitrate of silver; in 5000 parts of water a yellowish white precipitate; in 50,000 parts of water a white turbidity; and in half a million parts of water a scarcely perceptible opalescence. A soluble chloride, or hydrochloric acid, produces opalescence in a solution of one part nitrate of silver in 120,000 parts of water. This is scarcely perceptible if diluted 400,000 times, whilst if diluted 800,000 times, the an opalescense does not show itself for a quarter of an hour. The photographic properties of nitrate of silver are too well known to need further notice at present.

The adulterations, intentional or accidental, of this important chemical, are next to be considered. Nitric acid is a very common ingredient of the cheaper varieties, and may easily be detected by the smell. Some varieties of commercial nitrate of silver contain so much of this impurity as to corrode the corks of bottles in which they are kept. The remedy is to heat in a water bath, as previously recommended in the preparation of the pure salt, until all acid smell has disappeared, and then to recrystallise. Nitrite of silver is also very liable to be present on the fused compound being produced, if the heat has been rather too high in this operation. It may be removed by adding a little pure nitric acid to the aqueous solution, boiling down till it is nearly dry, and then heating on the water bath till quite dry and free from acid.

Organic matter of different kinds is very frequently an impurity in the commercial salt. It finds its way in from a variety of causes. Mr. Hardwich states that silver reduced from the chloride may contain organic matter which ultimately finds its way into the nitrate of silver. The remedy for this is to fuse the silver, or at least to raise it to a red heat in the air before dissolving it in nitric acid. In the solution of silver on the large scale in nitric acid it is sometimes customary to throw lumps of charcoal into the liquid when heated, in order to prevent concussive ebullition, which might endanger the safety of the vessel and its contents. Nitrate of silver thus prepared is valueless for delicate photographic purposes, until it has been purified by fusion and crystallisation.

Nitrate of copper may find its way into the silver; nitrate if the latter is prepared from the standard alloy. This may be avoided by taking more pains in the preparation to prevent the copper from remaining with the silver. If the salt, after evaporation to dryness, should, however contain copper, which may be known by its having a green tinge at the edges, the best plan will be to fuse the salt at a temperature a little below redness. The nitrate of copper is thereby decomposed, leaving black oxide of copper, this may be separated by solution in water and filtering; the filtrate after addition of nitric acid may be evaporated to dryness and heated as above recommended.

Amongst intentional adulterations we may mention nitrate of potash, nitrate of zinc, and nitrate of lead. These may be detected in the following manner:—Dissolve a drachm of the suspected salt in half an ounce of distilled water, and add pure hydrochloric acid until no more precipitate is formed, agitate well and filter off. The solution will contain the hydrochloric acid which has been added in excess, free nitric acid resulting from the decomposition of the nitrate of silver, and the nitrates which have been used to adulterate the silver salt with. This may now be evaporated to dryness, and if any solid residue is left it shows that an adulteration of some kind or other is present: in this case it will probably be thought advisable to ascertain what it is. It must, therefore, be dissolved in water, and have a drop of dilute sulphuric acid added to it, when, if a white turbidity is produced, it shows that nitrate of lead has been the adulterant; in this case add more sulphuric acid until no more precipitate is thrown down, and, after agitating the liquid again, filter it into a clean glass. If, however, no precipitate has been produced by the sulphuric acid, it need not, of course, be filtered. In either case evaporate the solution to about one-fourth of its bulk, and then add ammonia until it is in slight excess; then add a few drops of sulphide of ammonium, and if a white precipitate be produced it shows that nitrate of zinc has been present. If no precipitate, however, appears, evaporate the whole to dryness and heat the residue to dull redness until no more white fumes are given off. Any residue remaining behind, which will not volatilise at a temperature below redness, will show that an alkali is present. probably potash, showing that the silver salt has been adulterated with nitrate of potash. If the latter impurity only is present, the silver salt may still be used for making the sensitizing solution for positive printing. The only effect which it will have being to diminish the amount of silver present, which must be allowed for by taking more of the salt. It may also be used for making the nitrate bath for all except the most delicate processes. If nitrate of zinc be present, the salt will be fit for positive printing purposes, but will not be so suitable for the collodion process. Nitrate of lead and nitrate of copper will each of them render the nitrate of silver unfit for use in any photographic capacity, and it should either be returned from whence it was purchased, or purified. We have already explained how to separate copper from it. The separation of lead is a matter of more difficulty, the best plan will be to dissolve in water and precipitate the silver in the metallic state by means of a sheet of copper. The resulting silver must then be well washed to free it from adherent copper and lead salts, and then fused or heated very strongly in the air. It may afterwards be converted into silver nitrate as explained in former chapters.

DISCUSSION ON ALBUMENIZED PAPER AND ALKALINE GOLD TONING.

OPENING PAPER BY C. JABEZ HUGHES.*

The principal troubles met with in alkaline gold toning may be embraced under the following heads:—

Weakness and flatness of image.
Mealiness.
General greyness of tone.
Red spots and streaks.
Blisters.

Weakness and flatness of image is generally caused by the negative being deficient in contrast.

One peculiarity of toning by this method is, that a good print can only be obtained from a *good negative*. By the old method, a passable one could be got from a weak negative, by over-printing and reducing in the toning.

Generally, however, a weak and flat appearance is indicative of the silver solution being too weak. This use of a weak silver solution is one of the greatest causes of trouble. I take this opportunity of urging, as I have already done elsewhere, the use of the little instrument known as the hydrometer silver-tester, for estimating the amount of nitrate of silver in solution, every morning before sensitizing paper. No person knows, unless he has tested how rapidly the silver is abstracted from their bath by sensitizing paper. If objection be made to the instrument I have named, then use one of the other argentometers; they are all good and efficient, only do use some one of them.

A general greyness and coldness of tone.—Over-toning is the general cause of this. Not being exposed long enough in the printing frame, and being kept too long in the toning solution, will always produce this effect. The remedy is obvious. Papers excited on weak silver solutions have a constant tendency this way. Some papers are more subject to it than others, and on some Saxe papers it is too easily produced. Rive papers do not go into the inky tones, but adhere to the purple brown tints.

A general mealiness.—This at first sight appears to be a defect in the albumenizing, and yet it really is not so, for neither the albumen or the albumenizer is at fault, but the plain paper. It took me some considerable time to establish this fact, but I am quite convinced of it now.

This defect exists principally in coarse paper. When laid on the albumen it absorbs it unequally, and when dried the surface is seen full of small hillocks and hollows arising from this unequal absorption. Now as the gold requires a uniform surface of albumen to produce a uniform tint, it is seen that it cannot be obtained here, for the valleys, so to speak, tone first, and as they have less albumen on them, they are finished before the hillocks scarcely begin; the print taken out at this stage is covered with minute red spots of untoned albumen; now let it be replaced, and the toning continued till these spots are the desired colour; by this time the valleys are over-toned and have turned to a lighter grey, and the picture has that unpleasant speckled and dotted appearance, as if it had been dusted with fine flour, and in rubbing off, it had got ground into the pores of the albumen. Paper having this defect should be condemned, as, although it may be modified by manipulation, it never gives good pictures. *Rive* paper is very rarely subject to this objectionable peculiarity.

Red spots and streaks.—These are often caused by the paper being badly albumenized, and are then defects of manipulation; but they are often to be attributed to irregularities in the surface of the primitive paper, some parts absorbing more than the rest, and in toning, as the gold changes the colour just in the proportion of albumen present, so the difference of colour produced registers the exact amount of albumen, the red spots, lines, and patches shewing the irregular amount of albumen present. Remedy: better paper.

Blisters.—The defects hitherto pointed out belong mainly to German paper, but blisters are more prone to the thick Rive papers. The albumenizer is often charged with these, as though they were his fault. He is no more accountable for them, often much less, than the person who uses the paper. They range in size from a pin's head to a marble, or larger. They may be found in any very highly albumenized paper, and *only* in that description, and are less frequent in thin than in thick papers, being scarcely ever found in thin Saxe, and most abundant in thick Rive. These blisters usually take an oval form, and seem to be formed by a gas being generated in the body of the paper, which by its dilation, causes the soft and elastic albumen to expand also. The paper however splits into two layers, one portion remaining attached to the albumen. As a rule the greater the relative amount of carbonate of soda present, so is the tendency to blisters. Many papers will blister when a large quantity of the carbonate is added to the gold, which, if the latter be used acid or neutral, will not blister at all. This quite favours the idea already named as to their probable origin, for if the soda base unite with any of the acid sizing material in the body of the paper, the carbonic acid in struggling to escape would cause the distension of the albumen surface, and thus obviously explain the presence of blisters. They generally go down in drying.

I think I have pointed out the principal defects complained of, and apart from ourselves and our own defective manipulation, the great cause of the difficulties lies in the very plain papers themselves.

Those who albumenize paper must endeavour to have some control over the sizing, so that they may guarantee a more uniform article. Many persons think that the faults lie with the individuals who albumenize the papers. This is a mistake. These persons, when they prepare a large batch of albumen, float thin and thick paper, Saxe, English, Rive, all on the same albumen, in fact, treat them all alike; but the papers, as you know, all give different tones. Much less is in the albumenizer's domain than is supposed. Speaking of albumen, there are many false notions extant. Gelatine, dextrine, gum arabic, &c. are supposed to be added to albumen to increase the glaze; and many faults are attributed to these sources; whereas I believe that no substance whatever, chloride and acetic acid excepted, is added to the albumen, in this country at least. The cause of those bad smelling papers is decomposed albumen, than which few things have a more fœtid odour.

Not long since, one gentleman, who ought to have known better, burst forth with a grand panacea for all our troubles; a something which, if added to our albumen, everything was to go right, and without it all formulæ were hopelessly wrong. After this grand flourish of trumpets, and when on the tiptoe of expectation, we were told to wait a fortnight —a whole fortnight of anxious suspense, for the secret was too great to be hurriedly told—when, wonder of wonders, the mountain commenced its labours, and, *a few drops of acetic acid* oozed out. This, added to albumen, was to be a cure for all the ills albumen was heir to. Jesting apart, for the matter can only be so treated, despite the oracular method of its utterance, and the ponderous effort to astonish the world whatever small merit the addition of acetic acid to albumen may have, has long been known and is constantly practised. It does aid in producing limpidity, and, perhaps, tends to keep the whites clear, but it is so utterly inefficient to cope with the greater difficulties already named, that, while acknowledging its humble aid, all its extraordinary merits I dismiss to the safe keeping of the gentleman who made the discovery.

In leaving the matter in your hands, for I have only attempted to open it, allow me to say, that although we have troubles with our paper now, we are not peculiar, and need not despond, for troubles with paper have always existed. In early calotype days the cry was, where can we get good paper? The present are not the first complaints on printing. When the first novelty was past, producing prints at

* Continued from p. 67.

all, complaints were made of the foxy hue and dead sunken-in effect of our prints. Albumen was then introduced to give a finer surface and greater brilliancy. This was all very well, but there remained the odious colour, something between brick-dust and gingerbread, when that awful mystery of "toning" was invented, and we first got glimpses of that "beauty which only leads to destruction." During that brief period how we revelled in our new-born powers. Who would not be a photographer to produce such tones, such blacks, such whites? You remember that famous "Crucifixion." What a delusion we laboured under then? It was as though we had bargained with the Evil One to have temporary good for permanent ill — selling for fleeting beauty all future permanence. It was an awful "sell," that villainous mixture of sulphur and acid, and hypo and gold, and silver and chloride, and nitrate, and—what not. That ominous black pool, thick with ooze and slime, and fearfully suggestive, by its very brimstone smell, of the dreadful fate reserved for the young print, just fresh from the printing-frame, full of its fresh purple beauty. See, it takes the fatal plunge deep into this black ditch, and when we see it again, its virgin charms are all gone; wan and pale, disrobed of its early attractions, there, in that dark pool, it must in penance lie, till, forgetting its former self, it emerges, sallow in hue, black in shadow, a delusive beauty in its face, disease at its heart, a mockery, a delusion, and a snare, and fitting triumph of the demon—Sulphur.

Let us hope that these times are all past, that, in a photographic sense, the golden age is at hand, when our beauties will be as permanent as they are true. It is true some few of us still linger and look back fondly at the good old hypo times, who are sceptics as to the "good time coming," who sigh for the flesh-pots of Egypt; as an off-set to these—the archæologists of photography—let us point to the noble monument existing in the present Photographic Exhibition, where the few sulphur-toned prints present show up, by very contrast, the splendid success of alkaline gold toning.

Photographic Tourist.

PHOTOGRAPHY IN JAVA.

ACCOUNT OF A SHORT PHOTOGRAPHIC RAMBLE THROUGH THE INTERIOR OF THE EAST END OF THE ISLAND.

With our minds elated by the prospect of a pleasant trip, through the wildest and most beautiful scenery of Java, and with a first-rate supply of apparatus, including one of Smart's dark tents, which we had just received by mail from England, and in which we anticipated pleasant working, we (a party of three) started from Kedirie, an inland town of Java, at the close of a hot day, for a sugar station about eight miles on our road, and arrived with the decline of daylight at this, our stopping-place for the night.

The scenery on the way so far (the road being principally through a flat country composed of tawahs, or rice fields), presented nothing of interest to us in a photographic point.

Our host, Mr. Boyd, a Scotsman, received us with true British hospitality, and after entertaining us with all the amusement the place could afford in the shape of two dancing-girls, whose monotonous and unmusical voices soon wearied us, we (it being a fine moonlight night) proposed to take a stroll, but were prevented by our host informing us that the neighbourhood, within a few yards of the gate, was infested by tigers, so, after a long conversation on the dangers of the place, we retired for the night.

By daylight next morning we started off our coolies with the traps, but being a wet morning we delayed our departure till later on in the day, and after thanking and bidding adieu to our kind host, we started accompanied by eight or nine Javanese, mounted on horseback, as, having to pass a celebrated tiger haunt, it was not considered advisable to allow us to travel alone. The wildness of the place, being through tall jungle grass some twelve feet high, and so thick as to prevent the possibility of seeing more than a yard into it, and with the name it had got, altogether made this part of the journey rather exciting, even the horses seemed to have an instinct of danger.

After a cool ride through deliciously shaded coffee gardens, filled with monkeys and wild pigs (which from their impudence might well have been mistaken for tame ones), we arrived at Paree, where it was our intention to stay for a few days, having heard of some ruins in the neighbourhood, there also being a pasangrahan, or house kept by Government for the accommodation of travellers, where we could make our home for a short time.

The first object of interest which attracted our attention on arrival was an immense specimen of the Waringhin tree, in height about 180 feet, and covering with its shadow a diameter of 150 feet, planted in front of the pasangrahan, and offering a fine subject for the lens, though on trial we found that from its immense size it was impossible to recede far enough away from it to receive it on the plate, even with a lens embracing a large angle.

This was our first trial of Smart's tent, and as we had previously worked in a native-made affair, found everything very convenient, and easily put up or taken down; the only thing that might be improved is the window, which, owing to its being placed too high, makes the development of negatives rather difficult, the light falling *on* the plate from above, instead of *reaching it* from *below*. The india-rubber folding-tray and washing-bottle will not stand long in this place, as on opening them they are generally all stuck together, and are with great difficulty separated. The tent is as good as can be desired for working wet collodion, with these exceptions, the latter of which would probably not occur in an European climate.

On the morning after our arrival we were waited upon by the chief of the village, to whom we expressed our wishes regarding his assisting us with men to enable us to find the ruins; after arranging everything for the journey to one of the temples he left us, and on the following morning we started. Our way lay through a forest such as we had never before seen in Java, lofty trees, each composed of hundreds of stems twisted together, and at no great height branching off into the most fantastic shapes, throwing down feelers similar to the banyan, others so covered with the most beautiful parasites as to hide altogether the stem from which they sprang; the ground below so overgrown with ferns and an endless variety of small bushes, and the air of gloom and quietness that hung on everything, even though in the middle of the day with the sun at its greatest power, altogether formed a scene long to be treasured in our minds.

After a ride of two miles into the thickest part of the forest, through the narrow horse-track made by the natives, we arrived at the temple, which (though interesting, and covered with many fine carvings) was so hemmed in by trees as not to allow of a single point of view; so we returned, not however without having picked out a lovely bit of forest scenery on the way, which we determined to return and photograph the following day.

At eight o'clock the next morning we were on the desired spot (the coolies having gone on before us), and after pitching our tent proceeded to select the best point of view for a small rivulet prettily overhung by ferns and hanging rattans, making a nice picture; owing to the extreme darkness of the forest, on looking at the ground glass, it was almost impossible to distinguish any image, even using a half-inch stop, making it very difficult to focus, (I am now speaking of a view camera 7 × 9).

The first plate was exposed three minutes, but was much underdone for a negative, though in ordinary circumstances, and a well-lit view, fifteen seconds would have sufficed; by the time the next plate was prepared the sun had emerged from a cloud behind which it was previously hidden, therefore throwing a nasty glare on to one part of the view, putting the other by contrast into perfect darkness. I may here mention that having, in a country like this, to deal principally with foliage, we have found that to get anything like softness pictures must be taken in the shade, as where the leaves happen to be turned to the sun the consequence is a dense patch in the resulting negative; the glare of the sun, especially after nine in the morning, being so very dense, a large proportion of bromide in the collodion is also necessary to ensure softness.

This being the case, and having pitched our tent in a spot where there was no chance of a ray of sun penetrating, we sat down on a bank and waited patiently till that luminary should again be obscured, in the meantime amusing ourselves by watching the gambols of a troop of monkeys perched on a tree over-head, who, from the manner in which they regarded us, seemed to be much interested in our proceedings; a number of peacocks were also visible at a short distance.

The desired moment having at length arrived, we proceeded to try again, and this time succeeded in obtaining a perfect negative, though with the long exposure of five minutes; after taking a stereoscope of the same subject, we proceeded, during the interval of cloudiness, to take another view in the forest much more extended, which also turned out satisfactorily, and, being much better lit-up, was done in forty seconds, giving an opportunity of introducing the figures of two Javanese.

After having obtained four good negatives, two large and two stereoscopic, we packed up our tent and returned to breakfast at the pasangrahan, during our stay at which place we amused ourselves in the evening by shooting, there being plenty of game, including deer, wild pigs, peacocks, and many other birds, always taking care not to be out after dusk, in consequence of the number of tigers in the neighbourhood.

Our next day's destination lay at a ruined temple (said to be six miles, but subsequently proving three) at which place we arrived late in the morning; at first sight, in consequence of the ruin being so shaded, we despaired of obtaining a picture; but after walking round it we chose one corner, having a splendid background of trees, as being the only suitable point of view; as it was, the camera had to be placed within eight yards of the building, while the trees forming the background were some fifty yards away, testing well the depth of focus of the lens.

Our first difficulty was to obtain water, there being none in the neighbourhood, and without which we could do nothing, as the natives (thinking probably that we had come for the purpose of in some way or other desecrating their temple) refused to give us any assistance in obtaining it; however, on mounting to the top of the ruin for the purpose of examining it, we discovered a hole cut into an ornamental block of stone, which contained sufficient of the desired fluid for our purpose. In many cases we have had to use the water from the cocoa-nut, each of which will yield about a pint. After filling our water-bottle we took the view chosen, first on the large, and then on the stereo plate, with an exposure for the former of eight and the latter ten minutes, keeping the plate damp by means of a piece of wetted velvet thrown over the camera, which succeeds admirably well. There being nothing else of interest in the vicinity, we mounted our horses, and the road lying through sawahs (rice-fields) for two miles, with not the least shelter from the burning rays of the noonday sun, made the change from the shady coolness of the grove in which we had been working, anything but pleasant; the best thing in such a case is to gallop along, thereby causing a current of air, which is much preferable to prolonging the journey by slow travelling.

I will here give a detailed account of the apparatus which we take with us on a journey of a month or six weeks:—First, our tent, containing water-bottle, washing tray, &c.; a portable 7×9 folding camera in leather case, containing slides and lens, also a silk handkerchief for wiping off any dew that may form on the lens, on placing the camera in the sun; a deal box 15 inches broad, 18 inches long, and 15 deep, which contains a mounted glass bath, 8×10, filled with nitrate solution; one 7×9 and stereo plate box, each one containing a dozen cleaned glasses; two Burfield and Rouch's collodion pourers, each filled with two ounces collodion, ready iodized; three ten-ounce bottles, containing iron developer, cyanide solution, gold solution: three two-ounce bottles of acetic acid (glacial), pyrogallic acid, and a ten-grain solution of nitrate of silver for second development; besides these, cloths for polishing, focussing velvets, spirit level, lamp and matches, for drying the plates before returning to the plate boxes, and any other little thing necessary, such as a stand of gutta percha for laying the wet pictures on when taken; on the lid of the box is pasted a slip of paper, on which is written a list of everything contained therein, this we make a practice of examining before starting, so as to prevent the possibility of having to return for some such trifle as the lens or collodion, and by this means nothing is forgotten.

The camera, tent, and box, together with the stand, fit into a piece of basket-work, which, with a bamboo passed through it, is easily carried by four coolies.

We also have a box containing a relay of materials which is generally sent on before, this contains a stock of glass, of both sizes, in plate boxes, 1 twenty-ounce bottle of collodion, 1 twenty-ounce bottle of iodizer (forming, when mixed in equal quantities, an alcoholic collodion of the proportion of five parts ether, to seven alcohol), funnels, filtering paper, a stock of clean cloths, and an extra quantity of bath solution, in case of accident, complete the list.

(To be continued.)

REPORT OF THE COUNCIL OF THE PHOTOGRAPHIC SOCIETY.

In submitting to the members of the Photographic Society the Eighth Annual Report, the Council beg to congratulate them on the scientific position now attained by the Society, and on the general recognition accorded to it as representing photography in this country.

On presenting the Report for the past year, the Council trust that the efforts made by them to guard the interests of the Society, to uphold its position, and to promote its welfare, will meet the approval of the Members.

The plan of throwing open the rooms of the Society in order to promote social intercourse among the members, and to afford opportunities for study, although conceived in a spirit which met with general approval, was found unsuccessful when practically tested. It was therefore determined at the last Yearly Meeting, that notice should be given of an intention to vacate at Midsummer the premises occupied by the Society, at an annual cost of more than £300.

Through the courtesy of the authorities of King's College, a place of meeting more suitable, and equally convenient, was rendered available. The Council at once accepted the liberal terms, and trust that, both as regards expediency, and efficiency, the change will meet the approval of the meeting.

The expenditure entailed by retaining the premises in Coventry Street during the first six months of the year was unavoidable; but it may be now fairly assumed that the change of premises will materially reduce the expenditure.

At the last Annual Meeting, there was presented the Report of the Committee appointed to investigate and decide on the relative merits of such collodions as were submitted for examination under the only conditions to which such a committee could fairly accede. To sanction the admission of preparations without information as to the precise process of manufacture was of course unwarrantable; and to test the properties of collodion supplied in insufficient quantities to allow of thorough examination would have been merely wasting the valuable time of the gentlemen who undertook the investigation. The Council can only regret that specimens of the productions of the numerous makers of collodion were withheld, but think it right to mention that every detail in the manufacture of the preparation approved by the Committee has since been fully published, according to the terms of competition. The expenses incurred during the investigation amounted to nearly £50.

The Journal has, during the past year, chronicled in its columns not only the Proceedings of the Society, together with the Transactions of the Photographic Society of Scotland, but has also recorded the details of various new processes, and the latest inventions and improvements in the heliographic art, often accompanied with illustrations, and afforded information upon all current subjects of interest to both scientific and practical photographers. As a mere record of the Proceedings of the Societies, the *Photographic Journal* would have caused a heavy annual loss to the Society, as the expense of publishing their Transactions does entail on most scientific societies. The actual cost of supplying the Journal has amounted to £90 17s. 5d. The total cost of the year's printing and publishing has been made up by advertisements, which attest the almost universal adoption of photography as a lucrative art. There are now several publications devoted exclusively to photography where there was formerly only one; and to this cause the publishers attribute some diminution in the advertisements, which gives rise to the small loss on the Journal above mentioned.

The presentation to the subscribers of plates illustrating the processes of Colonel Sir H. James and Herr Pretsch, entailed an expense of £20. The specimens of the photographic process of Mr. Joubert, issued with the number for June, were presented by that gentleman for distribution, and involved no expense to the Society.

The loss standing to the account of the Exhibition for 1860 will, there is good reason to believe, not attend the admirable collection of Photographic pictures this year. The expenses of the Exhibition of 1860, up to the end of January, were about £60, and the receipts £76, leaving a profit of £16 only; whereas a clear profit (allowing for *similar* expenses) has accrued of £50 during the same period of the present Exhibition, when the long continuance of wet and foggy weather especially interfered with the success of an Exhibition held before the commencement of the season. The year which began so disastrously to photographers, was equally unfavourable throughout: of continuous bright weather, affording both the opportunities and stimulants to work, there was literally none; and to this cause may be probably attributed the dissolution of several Photographic Societies which had local habitations.

It is hoped that some of the members of these societies will, in the season now commenced, join the central society, as the observations of photographers working in the country, and away from towns, where "houses thick, and drains pollute the air," are especially valuable.

During the past year the Governments of this country and on the Continent have on several occasions officially recognised the importance of photography in ordinary scientific research, in advancing education, and in preserving authentic records of the stirring events of the time. The expedition which visited Spain under Government auspices, for the purpose of securing photographs of the eclipse of the sun, most satisfactorily maintained the high repute of English photographers. The results obtained evinced the scientific precision and exceeding skill of the gentlemen who represented this country; and we are proud to say that Mr. De la Rue, Mr. Vignoles, and others are members of this Society.

Photographers accompanied the brilliant campaign in Italy by Imperial command; and the choicest and rarest works of ancient art in the museums of this country and abroad are now, under Government orders, produced and made known to thousands by the aid of photography.

The Society desire to sound a note of preparation to the members of this Society and to English photographers generally. The photographic section will form an important part in the Exhibition of 1862; and the Council beg to suggest that every effort should be made during the forthcoming season to ensure that this country shall be worthily represented. The earliest information as to the arrangements of the Photographic Section will be published in this Journal.

The Council have felt sincere regret at the loss of their colleague, the late Mr. P. W. Fry. From the first commencement of the discovery, by M. Daguerre, of a process by which light was made to impress upon a silver tablet the images it illuminated, Mr. P. W. Fry became an earnest student of photography. He was amongst the small band who commenced their labours ere yet Mr. Fox Talbot's earliest *photogenic* (so called) processes were fully developed, and before the publication of the Calotype process. So earnest was Mr. Fry, that he purposely visited Falmouth to make the acquaintance of Mr. Robert Hunt, who was reported to have become one of the most successful of the earliest English photographers. Under Mr. Fry's auspices a Photographic Club was formed; and Mr. Cundall, who did so much towards rendering the Calotype a manageable process, and Mr. F. Scott Archer, to whom we owe the use of the iodized collodion, were frequently seen at those agreeable gatherings.

Eventually Mr. Roger Fenton, aided by Mr. Vignoles, conceived the idea of a Photographic Society. The suggestion was warmly entertained by Mr. Fry, Mr. Robert Hunt, and a few others. They were naturally desirous of enlisting Mr. Fox Talbot; and several preliminary meetings were held, at which Mr. Talbot was present. The object of these meetings was to endeavour to induce that gentleman to relinquish some of his claims in favour of the Photographic Society. Mr. Talbot, however, claimed so much, and, although professing liberality to the young Society, his conditions were in every way so stringent, that it was resolved (mainly on the representation of Mr. Fry) to reject the offer which Mr. Talbot, no doubt conscientiously, felt was all he could concede.

To the efforts then made by Mr. Fry and his friends must be referred the ultimate removal of the objectionable restrictions, and the freedom of photography from the shackles of the patent law.

Much discussion has arisen respecting the introduction of the use of collodion; and Mr. Fry's name has been mixed up with that discussion as if he were a claimant for the discovery of the collodion process. This Mr. Fry never was. The facts were as follows:—Mr. Hall, of Dartford, who purchased Schönbein's patent for the manufacture of gun-cotton, was the first to exhibit the film formed from the ethereous solution of gun-cotton: the collodion film so formed was used in the hospitals to protect abraded surfaces from the air. The beauty of this film attracted the attention of photographers; and many endeavoured to avail themselves of it. Collodion was spread on glass, on paper, and on other substances, and films of chloride and iodide of silver were precipitated on the collodion surface, and pictures (very poor ones) were obtained. The earliest use which Mr. Archer made of collodion was for the improvement of his paper surface; for, being then engaged as a sculptor, he saw the service photography would render his art; and as such he took up the study, that he might retain resemblances of objects which he had executed, and which would pass away from his hands. At length, at one of the meetings of the Photographic Club, held at Mr. Fry's house, some really beautiful specimens of collodion pictures were exhibited by Mr. Archer, being the production of a friend to whom Mr. Archer had imparted his discovery, and who had worked with much earnestness in carrying out Mr. Archer's original ideas. Some little time elapsed, and many pictures were circulated, before Mr. Archer developed publicly his secret of *uniting a solution of the iodide of potassium with ethereous solution of the gun-cotton.* Mr. Fry especially urged Mr. Archer on in his discovery, and rendered him the means of bringing it fairly before the public. By this happy discovery the collodion was made an active agent in the delicate process; and from this we date the great extension of the art of producing pictures by sunshine.

When Mr. Fox Talbot commenced his action against La Roche, Mr. Fry most zealously assisted the defendant. He left no stone unturned to bring into court a sufficient amount of evidence to show that the collodion process in no one example could be involved by Mr. Fox Talbot's specification; and very great was Mr. Fry's delight at the success which crowned his efforts. It is not necessary to speak of the many experimental modifications which were introduced into our art by Mr. Fry; several of them are recorded in the Society's Journal. To the late Mr. Fry, the Society owes much. He was one of its founders, and, to the period of his death, was one of its warmest supporters.

The Council have to express regret that the accounts for the current year show a considerable deficit, although the general balance proves that the Society has ample means to discharge all claims against it. Certain expenses, unavoidably incurred during the year (which have been referred to in detail), will be very much diminished, or entirely avoided, in future.

In conclusion, the Council have much pleasure in announcing that during the ensuing year there will be presented to each member of the Photographic Society a print selected from the present Exhibition.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 12th February, 1861.

The art-treasures of Mount Athos, to which I referred in a recent letter as having occupied Count Sevastianoff several years in photographing, and which are comprised in some three thousand negatives, are likely to be given to the world by the aid of one of the photo-lithographic processes. M. Lemercier, so well-known for his excellent lithographic establishment, has already attained very remarkable and excellent results, and their publication is looked forward to with the greatest curiosity and interest. Some proofs from a New Testament of the ninth century, printed on parchment paper, are issued as specimens, and leave nothing to desire. They fully equal the specimen of Colonel James's photozincographic process, given in the Photographic News some months ago.

It may be well to remind British photographers that the Paris Photographic Society's Exhibition will open at the *Palais de l'Industrie,* on the 1st of May next, at the same time as the Exhibition of Paintings. Exhibitors must forward their pictures so as to arrive here between the 5th and the 15th of April, addressed to the agent of the society, M. Laulerie, Rue Drouet, No. 11, or Palais de l'Industrie, (Champs Elysées) porte No. 1, *carriage paid.* As the pictures, when framed and glazed, are exposed to much risk of breakage in the transit, the society undertakes to have those which are sent simply mounted, framed and glazed in Paris, at moderate charges, but they must be forwarded as early iu the month of April as possible, as if delayed while in the framer's hands, and are not delivered at the Exhibition on or before the 15th of April, they will be rigorously excluded. Coloured photographs will not be admitted, nor those which are 'touched' to such a degree as to destroy their integrity as photographs. The works sent for exhibition will be submitted to the examination of a committee, who will decide upou their admission or rejection. The class of subjects which will find most favour as contributions from England, is, undoubtedly, landscapes, subjects possessing stroug local or pictorial interest. Neither portraits nor composition-subjects are likely to find much favour here, unless the former possess high individual interest.

Mr. Gaughain, in experimenting with immersed telegraph cables, finds that gutta-percha employed as a protecting envelope for the wire, so far from being a non-conductor, is, in fact, a conductor. He states that if the couducting wire were perfectly isolated, the cable would form a veritable Leyden jar so soon as it becomes immersed. By substituting shellac for gutta-percha in his experiments, he was enabled to obtain perfect insulation of the conducting wire. It was found that to charge a condenser through wire insulated by shellac, no appreciable lapse of time took place, while if charged through a wire coated with gutta-percha, fifteen miuutes elapsed before the condenser was fully charged; moreover, in the latter, the same length of time was required for the complete discharge; this, it is evident, must be attended with many serious consequences.

A remarkable improvement in street lamps results from the employment of M. Degrand's skeleton lenses. They are distinguished from all similar productions whether moulded or cut, by their extreme thinness. The reduction of their prominences is such, that they are, properly speaking, nothing but simple glass striæ, capable of being employed for glazing window-sashes, lamps, &c. It is a most extraordinary fact, that within the thickness of window-glass we can have lenses of all dimensions and of any focal distance, exactly the same as with the thick lenses of Fresnel. To obtain this result, it is only necessary to prepare a metal matrix or mould, presenting in its hollows, curvatures calculated to any required formulæ, and employ it to *strike* lenses as we do coins or medals, substituting for the metal thin pieces of glass softeued in the furnace. In the moulding, or striking of the lenses, M. Degrand employs with much success a bronze polish. The principal aim of this skilful engineer in the construction of his plane lenses has been the improvement of street-lighting, the diminution of the considerable loss of light in the atmosphere, or, in one word, to increase the effective light of lamps. Experiments conducted with the greatest care have proved that the interposition of a striated lens augmented the light of an ordinary lamp from 1 to 5·49. This result exhibits, most strikingly, the imperfections of the present system of lighting, and the advantages to be derived from adopting the new lenses. The expense of adopting them is very moderate. Applied to lighthouses, these lenses give results no less satisfactory; they absorb less light, spread it more uniformly, and reduce the cost of lighting fully one-half.

THE RECENT MEETING OF THE PHOTOGRAPHIC SOCIETY.

Sir,—I see in the report of the discussion at the meeting of the Photographic Society ,in the last number of the News, that "Mr. Malone, as a party to all the arrangements at the time, must repeat that Mr. Talbot never wished to throw obstacles in the way of amateurs using his process; he only made it a condition that they should not practise it for profit," &c.

My first experiments in photography were about 1842, with bichromate of potash, and when I thought of proceeding to the calotype process, I asked Mr. Robert Hunt, at that time one of the principal authorities on matters photographic, if I might do so, solely as an amateur. His reply was, that Mr. Talbot threatened with an injunction any person who used it, even for amusement, without a license from him. Accordingly I wrote to Mr. Talbot, stating distiuctly my wish to practise it as an amateur, aud without any view to profit, and received an immediate reply from his solicitors, enclosiug a copy of agreement which I should have to sign. In the first place there was a payment of £20 for the license, which, to the best of my recollection, might be withdrawn at any moment, and I was forbidden even to give away any prints to friends without Mr. Talbot's leave first obtained. To sell them was of course not to be dreamt of. There were other restrictions which I cannot at this distance of time recollect—but perhaps one of your readers may have a copy of the agreement. If so, it would not be without interest, and might help to refresh Mr. Malone's recollection.

Does Mr. M. mean to say that the fear of an injunction, or the payment of £20, was no obstacle in the way of amateurs? Happy man! to whom £20 is no object, and the threat of an injunction in Chancery has no terrors. In those days photographers had other than chemical and optical difficulties to encounter.

I don't mind acknowledging now, that after refusing to have a license, I straightway went and got a camera, and proceeded in my experiments, hoping that, as I was scarcely safe for the costs, Mr. Talbot would begin with some of those more distinguished amateurs, whom I had ascertained were practising his process under similar circumstances.

W. Russell Sedgfield.

Proceedings of Societies.

Photographic Society of Scotland.

The fourth meeting of the present session was held in the Society's Hall, George-street, on Tuesday evening. Sir David Brewster, K.H., F.R.S., President of the Society, in the chair.

Mr. Robert Armstrong, Photographer, 63, Princes-street, was elected an ordinary member of the society.

An interesting paper on "Photographic Portraiture," was read by Sir David Brewster, in which he pointed out the various defects inherent in portraits produced by the large lenses at present in use, and suggested the substitution of small sized lenses of rock crystal, as a means of obviating such defects to a large extent. With the view of giving an ocular illustration of the state of photographic portraiture, Sir David proposes to exhibit at the next meeting of the society a series of portraits of the same person, as taken by several of the most eminent photographers; as other members have promised their co-operation, several series of such portraits will probably be exhibited, and afford many curious illustrations of Sir David Brewster's views.

Mr. Horatio Ross announced the result of the competition for the Silver Medals offered as prizes for pictures in the Exhibition of the Society now open. Having been requested by the committee to officiate as judge, he said that he had devoted a great deal of time to the examination of the pictures, but had experienced the greatest difficulty in making up his mind, particularly as to the best landscape. He found a number of pictures by Maxwell Lyte; Annan, of Glasgow; Mudd, of Manchester; Fenton, Dixon Piper, and Vernon Heath—all as nearly balanced, in point of merit, as possible; and it was only after advising with various members, on whose good taste he could rely, and finding no preponderance of feeling in favour of any particular picture, that he felt himself warranted in awarding the prize to the picture which he himself preferred —"A View of Pierrefitte," by Mr. Maxwell Lyte, No. 106 of the catalogue of the Exhibition. In regard to the other medal he had not found so much difficulty; for although there were several admirable portraits exhibited by Mr. Tunnoy, Mr. Moffatt, Mr. Orange, and other photographers, he was of opinion—and in this view the friends with whom he had consulted concurred—that M. Claudet's portraits were the best, and he was chiefly at a loss to determine the particular picture for which the prize should be awarded; ultimately, he had fixed on the picture, No. 67 of the catalogue, "A Lady in a bridal dress." Mr. Ross, with the approbation of the Council, suggested that the society's bronze medal should be given to Mr. H. P. Robinson, for his excellent composition picture of a "Holiday in the Woods." This was cordially agreed to, and the thanks of the meeting voted to Mr. Ross for the great amount of trouble he hae taken in the matter.

The Honorary Secretary read a communication from M. A. Claudet, F.R.S., "On the Laws which Regulate the Conjugate Foci, and the Sizes and Proportions of Images, according to the Distance of Objects." In this paper, for which M. Claudet was complimented by the President, he pointed out the advantages which photographers would derive from being able to determine beforehand the exact position of the focus with reference to the object, and the resulting degree of reduction or amplification of image—he defined the positions before and behind the lens from which all distances must be measured for obtaining an exact proportion of perspective; detailed the means by which these positions could be practically and surely determined, and a scale established for every lens, which would show in all cases the focal distances corresponding to the distances of objects, and he gave various tables for applying the results so obtained.

The business of the evening concluded by the Honorary Secretary reading a paper by Mr. C. J. Burnett, in which he suggested several improvements in photographic etching; the use of aluminium for photographic apparatus, and methods for obviating the necessity of mounting photographs by printing them, so that the margin forms a part of the paper on which the picture itself is printed, and which he recommended as particularly convenient for photographic illustrations for books.

Photographic Notes and Queries.

India-Rubber for Baths, &c.

2, *Queen-sq.*, *Westminster, S.W.*, *6th February*, 1861.

Dear Sir,—I will now give you the promised particulars of the manufacture of baths of pure india-rubber.

Take a block of wood, the size of the bath to be made, and having procured from some respectable india-rubber warehouse (I prefer Messrs. Macintosh and Co. for the *purest* rubber) a piece of "stationer's cut sheet," about No. 13, the *exact* thickness will depend upon the size of the bath, cut sides and ends a quarter of an inch larger than those of the block, and lay them in their respective places on it. Now cut off the projecting pieces all along with a sharp pair of scissors, and it will be found that the scissors in cutting the double rubber at the corners have made a *joint* there, which will be sufficiently strong to enable the operator to complete the bath conveniently.

The india-rubber for the bottom should be *half* an inch larger than the bottom of the block, and pieces one quarter of an inch square should be cut out of each corner, so as to leave a space in the middle the exact size of the block, pieces a quarter of an inch wide will then be left to lap over the rubber, forming the sides and ends of the baths; now comes the operation of cementing, first procure some benzine (not ben*zole**), which can be had of any respectable chemist, and with a clean rag apply it to the quarter-inch flaps, and to the depth of a quarter of an inch round the sides and ends of the rubber on the block, which will then be found to be "tacky," now put the block upright in the middle of the bottom piece, and turn up the flaps against the sides and ends of the bath, and with gently rubbing the finger along it will form a perfectly water-tight and in other respects a very strong joint; the only things that remain to complete the bath are, cementing in the above manner four strips of rubber about half an inch wide over the temporary joints made by the scissors, and also cementing two tubes (one on each side of the bath at the *top*) through which wires are to be pushed; these wires must be about one inch longer than the width of the bath, so that they can be stuck into any woodwork about the operating chamber, and thus support it in a vertical position.

The above description is for a *travelling* bath, and, as I said before, can be rolled up and put into the waistcoat pocket; but for a bath for stationary purposes I should recommend rubber thick enough to support itself, jointed with thin rubber, or made as I have made mine, namely, a *wooden* case lined with very thin rubber, the advantage of which is that it can be turned inside out and throughly cleansed.

* Some confusion appears to exist in our correspondent's mind here. The terms *benzine* and *benzole* are applied indiscriminately, and both indicate the same article. Probably our correspondent may have been supplied with a more highly rectified sample of the solvent referred to, by a dealer who has applied the former term, and hence he conceives an absolute distinction to exist.—Ed.

I will make no further comment upon the qualities of an india-rubber bath, it will speak for itself.—I am, sir, yours obediently,
LEO. DAFT.

A SINGULAR FACT.

MR. EDITOR,—Believing that it is always advantageous to our delightful art to communicate our experiences, and more especially when they appear to be unusual, I am induced to trouble you with one of mine which I consider so, it never having occurred to me before, or come under my notice in any other way.

About a week ago, having to take a photograph of a small machine, I coated a quarter plate with Hardwich's collodion, and exhibited it as usual; but the glass being a very small one, one of the corners passed through the plate-holder, and to get it back I raised the slide, thus allowing the light to pass through the plate, when, to my surprise, I saw the front of a figure in a different (more transparent) shade impressed on the film, which a friend, whose attention I called to it, immediately recognised as part of the figure of a lady of which I had made some positive copies, one of which had doubtless been washed from this glass, though it showed no stain or blemish while cleaning.

To preserve it I exposed the plate for an instant to white light, developed with pyrogallic, and fixed, which has left the figure as if it had been exposed in the camera in those parts where it showed itself before exposure.

If you wish to see the plate I shall have great pleasure in showing it to you.—I am, yours obediently,
F. LANE.

103, *Southwark Bridge Road, 2nd Feb.* 1861.

[The phenomenon is curious. We have heard before of similar cases, but not often. We should be glad to see the plate.—ED.]

MAGNETISM AND PHOTOGRAPHY.

THE following extract, from an instructive article in the *London Review*, will interest our readers as bearing on the importance of magnetic registrations, and the beautiful application of photography to that purpose:—

We have discovered that electrical undulations are established upon the surface of the earth by the action of the solar rays, and that they circulate from east to west, varying in their intensity with the varying position of the sun relatively to the place of observation. That fine old Swedish philosopher, Oersted, proved the connexion of magnetism and ordinary current electricity, and demonstrated that all magnetic phenomena take place at right angles to such electrical paths. Thus we know now, that the magnet (the compass needle) points to the north and south, because the electrical circulation is from the east to the west, magnetism and electricity being always at right angles to each other. There is a continual variation in the *force* or *intensity* of the earth's magnetism; these variations—hourly, daily, monthly, and yearly—observing a certain degree of regularity, and exhibiting a peculiar dependence upon the relative positions of the earth and the sun.

Since every variation in the magnetic force of the earth produces some disturbance in the magnetic needle, it was important to determine with exactness the laws by which these laws were regulated. As the commerce of the world is materially concerned in the perfect appreciation of all that affects the mariner's compass, the great nations of Europe and America combined to establish magnetic observations in all parts of the globe.

The method of making a magnetic observation is to examine the number of oscillations made by a magnetic bar in a given time. It will be understood, upon reflection, that if a *magnetic bar*, freely moving, being attracted by the *magnetic earth*, is influenced by powerful force, it will move with more difficulty than when this action is weak. Thus the observer noted the number of oscillations made in each minute of time, during each set of observations, and these being carefully recorded, showed the amount of variation in the earth's magnetic force.

On one occasion when such observations were being made, the magnetic bar was seen to become suddenly agitated, to move more rapidly, and describe a larger arc. This could not be explained, but the fact was recorded. Eventually, returns were made from the other observatories, and a similar phenomena to that which took place at Greenwich was found to have occurred at Toronto, St. Helena, Kerguelin's Land, and other places, at the same instant of time. Humboldt gave to this kind of disturbance the name of a *magnetic storm*; and these storms were found to have a close connection with aurora. By the refinements of modern science, photography has been made to take the place of the observer, and by ingenious arrangements a ray of light is reflected from the end of the magnetic bar, and made to record, by the chemical change produced on photographic paper, every movement by day and by night, to which the bar may be subjected. By these means we have learnt that those magnetic storms are of frequent occurrence, and that they are simultaneous over hundreds and thousands of miles.

Some mighty and mysterious power influences the earth's electricity, and this is made known to man by the tremor of a magnetised bar. The intelligent observer solicits nature to reveal the secret of this, and after long and patient prayerful working, an answer is given. That answer telling us that the phenomena of magnetism, as manifested on this planet, is the continuation of a development of physical force, dependent upon changes in the form of matter which occur in the sun.

The sun's brightness depends upon a gaseous self-luminous envelope, to which Arago gave the name of the *photosphere*. This envelope is subject to peculiar disturbances, which are indicated to us by the formation of dark spots. These spots have been the subjects of observation since 1612, when Galileo made some important observations on them. Sir William Herschel, 1801, published a remarkable paper on the spots, and endeavoured to show that there was some connection between the number of spots seen in any given year on the sun's disc, *with the price of corn in the English markets*. But Hofrath Schwabe of Dessau has given us the most reliable information respecting these spots. During the long space of thirty years he has often examined the sun's disc for upwards of 300 days in each year. The tables which Schwabe has published leave no room to doubt that the solar spots occur in cycles of about ten years; the smallest number seen in any one year being 83, the largest number being 333. Five years are expended in advancing from the minimum to the maximum number, and five years again in descending to the minimum.

Schwabe writes:—"I do not believe that the spots on the the sun have any influence on the temperature of the year;" but he could examine only the results of a limited area. The enlarged observations of Dove, who was supplied with returns from every part of the world, go to show that there is a a connection between the variations of the mean annual temperature of the whole earth, and the production of solar spots. We have not, however, now to deal with heat, but magnetism. All the observations made at the magnetic observatories of the world, are returned to General Sabine, and carefully reduced by a staff of engineers, under his direction, at Woolwich. The result of the most careful examination has been, the announcement of the astounding fact, that the periodical inequality of the earth's magnetic force has its opposite phases of maximum and minimum, separated by an interval of five years, of which the cycle may be conceived to include about ten of our solar years.

The regularity with which the alterations of increase and decrease have been traced by Schwabe, in his observations of the solar spots, is found to occur in the earth's magnetism. "The coincidence," says General Sabine, "as far as we are as yet able to discover, is absolute; the duration of the period is the same, and the epochs of maximum and minimum fall in both cases in the same years."

We know not of any series of observations, within the history of modern science, which marks more completely the triumph of the human mind over nature than this. There certainly has never been developed to man a more exalting fact, or one which shows more completely the delicate balance maintained between cosmical phenomena. A disturbance takes place in the sun—which, in many respects, resembles our great revolving storms of the tropics—and this disturbance is communicated through millions of miles of space, and shakes the magnetism of the abode of man.

A SIMPLE MICROSCOPE may be made out of a common pill-box for a few pence. Take out the bottom and put in a piece of window glass; then paint the inside black, and make a small eye-hole in the lid. In this hole place a single drop of warm Canadian balsam, and allow it to cool. This drop of the transparent resin assumes, when cooling, the proper form of a glass lens, with considerable magnifying power.

Talk in the Studio.

Her Majesty at the Exhibition.—Her Majesty the Queen, and His Royal Highness the Prince Consort, accompanied by the Princesses Alice, Helena, and Louise, visited the Photographic Exhibition in Pall-Mall East, yesterday morning. In attendance were the Viscountess Jocelyn, the Hon. Caroline Cavendish, Lord Alfred Paget, and Lieutenant-Colonel the Hon. D. de Ros. Her Majesty, with her accustomed punctuality, arrived in Pall-Mall at just two minutes past ten in the morning, and remained nearly two hours engaged in examining the various productions, with which she expressed herself highly gratified.

The Architectural Photographic Exhibition.—An interesting lecture on the Photographs of French Gothic Architecture of the Thirteenth Century, was given by R. P. Pullan, Esq., on the evening of Tuesday last. The lecturer emphatically claimed for photography the position of a fine art, and for the cultivated photographer the position of an artist.

New Photographic Society.—A contemporary states that a new society is about to be formed in Edinburgh. A preliminary meeting has been held to consider the matter, and from the general opinions expressed, it appears probable that the meetings will be held fortnightly, and partake largely of a conversational character. A meeting for the election of officers &c., is to be held on the 20th instant at Buchanan's Temperance Hotel.

Crystal Medium.—A new application has just been made of the prepared sheets of mica, or crystal medium, sold by Messrs. Squire and Co.; it consists in using it instead of glass to cover the cartes des visite portraits. Being perfectly flexible it can be applied to these portraits, which are put up in flexible pocket cases, without the danger of breakage which would of course attend the use of glass. The application is useful and ingenious, and gives a pretty effect.

Domesday Book.—It was announced, at a recent soirée at Southampton, that the original "Post-Office Directory" for 1080, had been disinterred from the Record Office, and will, under the superintendence of Col. Sir H. James, be photographed *in extenso*, so that all good subjects of Her Majesty will acquire the important information of how many acres of land, horses, carts, beeves, and swine were possessed by the vassals of William the Conqueror. The process used will be Col. James' method of photo-lithography.

Photographs of Lord John Russell.—His Lordship sat for several negatives at his residence, Chesham Place, to the artist of the London Stereoscopic Company on Tuesday last. Some very fine portraits were, we understand, obtained.

The First Portrait.—The Prussian correspondent of one of our daily contemporaries writes:—Princes cannot but allow themselves to become famous, even in their days of nonage. I have to acknowledge the important fact that of the hundred pictures destined to perpetuate the features of baby Prince William, the very first has just made its appearance in the world of art. The portrait is a photograph depicting the son of our Princess, in the grave and solemn act of sleeping a royal sleep, and perhaps dreaming royal dreams. In the bookseller's windows in Berlin you may see the quaint little fellow in his cradle by the side of a still more serious picture, representing his late Majesty.

New Solar Camera.—*The Scientific American*—which we may mention in passing as one of the best papers of the kind in the world—describes another solar camera recently invented, in which instead of the mirror travelling with the sun so as to secure the same angle of reflection, the same effect is obtained by a series of mirrors:—The object of this invention is to obtain from photographic negatives of a given size, positive pictures of a much larger size. The invention relates to the employment of mirrors to reflect the direct rays of the sun through the camera containing the negative, and it consists in so applying and operating a system of mirrors or reflectors in combination with the camera, whereby, notwithstanding the movement of the earth upon its axis, the rays of light will continue to be reflected in the same direction for as long a time as may be necessary to obtain the print, and distortion of the picture be prevented. The credit of this invention is due to J. H. Whitley, of Oswego, N.Y.

To Correspondents.

A. H. Scott.—M. Lejune's plate-holder, described in the News for May 28th, is there stated to be manufactured by Messrs. Gaudin. Beyond this we have no information on the subject.

Ricardo.—The statement of "S.S.B." on the number of pieces of wire-gauze necessary to prevent regurgitation of the flame in the oxyhydrogen apparatus, may be relied upon, as coming from one thoroughly experienced in the matter. We have not tested practically the various suggestions of our correspondents as to the magic lantern. We can only refer Ricardo to what has appeared in our pages, and leave him to select the plan best suited to his appliances.

S.B.—In taking stereoscopic pictures with a camera, on Latimer Clark's principle, it is necessary to adjust the position of the lathes by means of the screw to suit the distance of the object to be taken. Observe that the image occupies the same position on the ground-glass which-ever position the camera may be in. The two pictures should not be much more than about two inches and a half from centre to centre; if they are at a much greater distance, the eyes of most persons will have difficulty in making the images superpose so as to produce the proper stereoscopic effect. A few experiments with the adjusting-screw, and observing the effect on the ground-glass, will enable you to produce the proper result. 2. White, or blue calico, answers well for the blinds of a glass-room.

A Junior Photographer.—The *Photographic Quarterly Review* is discontinued, and there is no other quarterly journal of photography. There is no monthly photographic periodical except the *Journal of the Photographic Society*; the price of which by post is sixpence.

X.—The patent pressed lenses are to be procured, we understand, from Messrs. Chance, Brothers, of Birmingham. They are somewhat expensive, a lense of 12 inches diameter costing about £15. We apprehend that a much less costly condenser might be used for the purpose indicated.

Lex.—You may photograph copyright engravings for your own private amusement; but if you sell a single copy you are liable to an action.

B. B.—Under-exposure and dirty plates are the palpable causes of your failure.

James.—The time necessary for a plate to remain in the bath varies very much with the temperature. It may generally be safely removed as soon as the solution flows evenly over the surface, instead of running in greasy streaks. If left too long in the bath, the plate has a tendency to fog.

M. M. E.—The unfavourable weather which has prevailed for so many months has proved an almost insuperable barrier to experiments with the solar camera.

E. J.—Use fresh starch for mounting. The tendency of albumenized prints to curl up before they are mounted is sometimes very troublesome. To overcome the difficulty take a parcel of the prints and roll them up for a few minutes in an opposite direction.

Positive.—Excess of nitric acid in your developer will cause the picture to be covered with metallic spangles. A small portion of nitric acid will give a more metallic tone to your pictures; but beware of having too much.

W. Cox.—Doubtless any optician could supply you; but we will make some definite enquiries as to price &c., and let you know in our next.

W. W. M.—See article in the present number on the application of the Lime Light to the Solar Camera. If that does not meet your case, let us know, and we will enter into the subject.

D. A.—We should as readily purchase either No. 1 or 2 as any of the others. In selecting a large lens it is important to have a good one. If you send us your address we can give you more particulars by letter.

W. H. L.—We have no doubt but that Ponting's Collodion will work very well for a dry process, if you add from half a grain to a grain to the ounce of bromide (of ammonium in preference to cadmium as the collodion already contains cadmium in the iodide). 2. Your failure probably arises from using a simply iodized collodion. It is important to have a second salt of silver in the film in the dry processes in which all, or nearly all, the free nitrate is removed. 3. The brown deposit is probably gold. We prefer to make the toning solution fresh, using just sufficient for the prints, and not using it twice.

No. 35.—There is a new edition of Dr. Hassall on adulterations, published this year: the price is 17s.6d. There are various good works on the microscope besides those you possess; amongst which we may name Queckett, price 21s. The Micrographic Dictionary price 45s. West's half hours with the Microscope, price 2s.6d. &c. We cannot just at this moment say which will contain all the information you require.

1. 2. 3.—The stains on your negative appear to proceed from the bath, which is not in good order. A bath saturated with acetate of silver is difficult to manage, especially when it becomes old and contains an accumulation of ether and alcohol. Try the addition of a minute dose of nitric acid. Try also another sample of collodion. The deposit on the surface of positives which brushes off, arises from over reduction. Add a little more acetic acid to your developer.

F. R.—Lime balls are sold in bottles containing a dozen for 2s. 6d. You may make them cheaper by procuring lime by the bushel, and picking out the suitable pieces, and sawing them to a proper length. They are then rasped roughly into shape, and finally fitted into a mould of wood to finish them to the exact size and shape.

J. H. Jones.—We are obliged by your communication, and will write to you shortly.

T. Waawick.—We do not know what kind of dirty stains you mean. A dilute solution of oxalic acid will answer the purpose in some cases. Rubbing with a piece of cuttle-fish bone will answer in other cases. The best means of rendering a rough surface smooth is by means of rolling or hot-pressing.

W. A. Y.—Use the calotype process. The exposure of excited paper in an ordinary enlarging camera is somewhat long. Prepare the paper by first floating on a solution of—bromide of potassium, 12 grains; iodide of potassium, 8 grains; and then excite on a 60-grain silver bath. Expose whilst moist, and develope with a solution of gallic acid. Use Hollingsworth paper. 2. Your collodion will never be so good as it originally was. The best plan now is to mix it off with new collodion, whereby both may be improved.

H. T. T. and others in our next.

N. M. Mathews we will communicate by post.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 129.—February 22, 1861.

PRINTING BY THE ELECTRIC LIGHT.

Since the opening of the present Exhibition, and too late for either regular hanging or insertion in the first edition of the catalogue, Mr. Bedford has contributed a frame of three photographs, which to us possess an interest equal to, if not surpassing anything in the room. These three specimens, No. 623, are printed by the electric light, Professor Way's valuable modification having been used. The first impression on glancing at the frame is that it simply contains some of Mr. Bedford's prints, the only peculiarity of which is their excellence. The fact of there being copies of the same prints already on the walls induces an examination to ascertain why this duplicate frame stands in front of the Curator's table, and then it is found that the modest information is subjoined, that they are printed as we have stated, and that they are the result of a first trial. The latter part of the information need not be understood in any apologetic sense, for the pictures need no such plea: they are as brilliant, vigorous, rich, and perfect as need be desired; and so far as the gas-light comparison we made may decide, equal in all respects to the same pictures produced by sun-printing.

Our readers are aware that printing by electric light has before been accomplished. The interesting paper read a few months ago by Mr. Malone, and published in our columns together with the results he showed, demonstrated the possibility of the process; but we have not before seen absolutely perfect pictorial results produced by such agency, and under conditions which attest that this experiment need not remain an isolated one, illustrating a curious and inapplicable possibility; but affords good assurance that the process may be brought quite within the commercial exigencies of the first-class photographer.

Mr. Bedford has favoured us with a few details of the conditions under which these pictures were produced, which are to us in the highest degree interesting, and cannot fail to be so to photographers generally.

Our readers are already aware of the peculiarities of Professor Way's lamp, which have been described in previous articles.* One of its advantages over the Duboscq and other electric lamps being that the perpetual flow of the fine stream of mercury gives a light perfectly continuous, whilst where the carbon points are used the light is intermittent. The chief peculiarity and advantage to photographers arise out of the nature of the light, which possesses great volume, instead of appearing as a single vivid point; and, of still more importance, that it possesses, in a much greater degree than the electric light produced by other means, an intensely actinic character, which gives it a peculiar value for printing purposes.

The pictures now exhibited, Mr. Bedford informs us, are not only the result of a first trial, but that trial was made under circumstances somewhat unfavourable for success, the lamp being an imperfect one, and all the arrangements of an improvised and temporary character. The printing-frames were suspended about twenty inches from the source of light, and the exposure required was a little upwards of an hour, the negatives being somewhat dense and the paper prepared as for ordinary printing. One especial point that strikes us is a remark made by Mr. Bedford, to the effect that the light possesses a peculiarly penetrating power, readily finding its way through the densest portions of dense negatives, thereby giving more detail in the lights than can be obtained by diffused daylight. Here, then, is a valuable source of power to the artistic printer, by which every class of negative may receive exactly the treatment it requires. If it be dense, and require a penetrating light to bring drawing into what would otherwise be snowy patches of light, it can be brought near to the source of light, the most penetrating power of which it may then receive. If the negative be soft or weak, by removing the printing-frame some distance from the source of light, all the effect of diffused daylight may be obtained; and this may be graduated to suit any character of negative. Here is a power of the utmost value to the printer quite under his control.

Regarding the cost of the light, Mr. Bedford informs us that in this intance the expense was about two shillings per hour, and adds, that "as it would be an easy matter to arrange a goodly number of frames around the light, it might be worked economically." Various details as to the best method of working, at the least cost, and questions regarding the best method of preparing the paper, &c., must necessarily be elucidated by further experiments; but we think that this "first trial" of Mr. Bedford's establishes the fact that the thing can be done, and that it may, at least, under many such circumstances as Mr. Malone on a former occasion adverted to, be done so as to be commercially remunerative. Mr. Bedford emphatically remarks, "I am convinced that the light is suitable for our purpose; it only wants utilizing."

M. Lacan, in an interesting letter to a contemporary on the same subject, describes some experiments made by a well-known Parisian photographer. In this instance Professor Way's improved lamp was not adopted; but one in which the old principle of carbon points is used, with an arrangement to keep them in contact. M. Lacan's description is interesting, but scarcely affords much encouragement as to the use of the light for portraiture. He says:—

I was present on Thursday last at a series of very curious experiments made by Nadar, in his new operating room, for the purpose of applying the electric light to photography. I found there a numerous party of men of letters, artists, and even practical photographers, all desirous of learning the results to be obtained from the alliance of the two great modern discoveries. The first essays were for obtaining negative portraits. The model—I had almost said victim, the operation was so long and tiring—sat at about two metres and a half* from the focus of light, and was placed so as to be lighted from above and a little to the right, while white screens around, and a large mirror on the shady side, sent back upon him the diffused rays. The light is very intense; the moments of intermittence are rare, and arise solely from the impurities of which they have not been able to entirely rid the charcoal. Three portraits were taken, the *pose* for the first lasting one minute and a half, for the second eighty seconds, and for the third forty-five, which appears sufficient. The collodion employed is not peculiar. The developing is done, as usual, with pyrogallic acid.

Experiments were next made in producing transparencies on glass by means of camera-printing and wet collodion:—

The printing apparatus had been composed as well as could be managed for the occasion, by placing opposite to each other a fixed camera and a telescope one, the space unavoidably left between them being covered with pieces of stuff. This extemporised apparatus was placed so that the negative was at about fifty centimetres† from the lamp. At the other extremity were

* See articles "Scientific Gossip," pp. 230 and 268 in our last valume, as well as some other articles.

* A little more than eight feet.

† Not quite twenty inches.

successively introduced several sensitised glasses, whose time of exposure was varied. Four seconds, with pyrogallic acid development, gave very satisfactory pictures. With a fine *cliché*, in which the contrasts between the lights and shades are not too violent, the exposure may be reduced to three seconds.

For the preparation of the glasses a collodion somewhat rich in pyroxyline is made use of. The image is developed by means of a weak solution of pyrogallic acid, avoiding as much as possible the addition of nitrate of silver. The exposure ought to be tolerably long for the image to appear in all its details. In the solar light, according to the author himself, the time of exposure varies much, but is never less than twenty seconds, which would give a great advantage to the electric light. The image is fixed with hyposulphite of soda, or, still better, with cyanide of potassium. After the fixage the picture is very beautiful by transparence, and, if it is desired that it should remain in that state, washing and drying are all that is necessary. Viewed, on the other hand, by reflection, it is of a disagreeable grey tone. This inconvenience may be obviated easily in the following manner:— A solution of bichloride of mercury is poured upon the glass. The image first becomes black, then white: when it has acquired a very uniform tint, a weak solution of ammonia or of hypo is poured upon it. The tone then becomes very vigorous, but pales a little in drying. There must then be applied upon the collodion a layer of white, which is to form the ground of the picture. For this, the white is diluted in a mixture of copal varnish and benzole; then spread over the glass, just as a layer of collodion. Being very even, it dries rapidly. The picture may be kept in this state, and produces a good effect; but it is preferable to transfer to paper, which is easily done by fixing a sheet of white paper upon the colour, and then letting it dry: the whole may then be taken off without difficulty. The image has a good deal of brilliancy, and looks as if it were covered with a layer of gelatine, if a well-polished glass has been operated on. We saw this transfer made very rapidly at Nadar's, notwithstansing the unfavourable conditions.

The lamp used is described as one of M. Servin's, which is very portable and convenient, and was connected with a battery of fifty elements.

From the description here given, and many other considerations, we think it is clear that the electric light is scarcely likely to become applicable for the purposes of portraiture. Its practical advantages lie in another direction. M. Lacan sums up the matter in the following conclusions:—

The light with which Nadar operated the other evening costs him fifty francs each time, whereas the light of the sun, in all its abundance and fecundity, is offered gratuitously to all who will turn it to account. Further, the results obtained in this manner, as far as negatives are concerned, can never be equal to those produced by the solar light. Still, there are many cases in which the electric light would be a valuable resource: for instance, when dark interiors or tombs in cathedral vaults have to be reproduced, or when one is called on to take portraits after death, in rooms into which but a feeble daylight penetrates. Its most important use would be for the printing of positives, especially if a means of sensitising gelatine were discovered, so as to permit of the employment of one of the carbon processes. There would be economy of time, as the night would become available; and, at the same time, the certainty of strength in the pictures. Lastly, this means would be applicable to magnifying apparatus, the principal inconvenience of which is the impossibility of using it without the direct light of the sun. With the electric lamp we should be independent of the collaboration of the capricious luminary, and should be able to operate at any hour and in any weather.

THE HYDROMETER BATH TESTER.

The uses of photographic societies and of photographic journalism sometimes receive curious illustration. Whatever may be regarded as new in principle, or useful in practice by one photographer, by the combined means of societies and journals soon becomes the common property of all photographers. But if the supposed New be Old, or the asserted Useful be doubtful or deceptive in practice, it is by the same agencies at once denounced and exposed, to the advantage of the photographic fraternity at large, and the confusion of its unlucky advocate. This system has undoubtedly its benefits, and furnishes, in the main, the surest guarantee for the sound and true progress of the art. It has, however, its partial evils, which are illustrated when reliable guides, and valuable practical conclusions, are thrown into temporary discredit, by the publication of statements based on assumed data and inconclusive experiments.

A discussion on silver meters, which has just arisen, is a case in point. At a recent meeting of the North London Society, Mr. Hughes read a valuable paper on the subject. based upon a series of experiments, the execution of which we had the pleasure of witnessing and verifying, and to the careful and intelligent performance of which we could bear ample testimony, did not the high authority of Mr. Hughes' name, and his well-known practical ability, render it unnecessary. The result of these experiments is a recommendation to photographers to use occasionally, for exact verification, a test based on chemical analysis; and for daily printing purposes, as a sufficiently reliable approximate guide, a test based on the known specific gravity of a given amount of nitrate of silver in solution. Mr. Cramb, a gentleman regarded, we believe, as a clever photographer in his district, is dissatified with these conclusions, styling them, with more force than elegance, "complete befooling," and having set himself right at the outset by a confessed foregone conclusion, enters into a series of experiments, the results of which he lays before the Glasgow Society.

We have no intention of entering into any lengthened examination of the results of Mr. Cramb's experiments, nor of the question at large. That we may leave safely in the hands of Mr. Hughes, who is, we believe, engaged in a series of exhaustive experiments, to give to his conclusions as thorough a scientific completeness, as they have already a practical value; but we wish just briefly to suggest one or two of the sources of error into which Mr. Cramb has fallen, in order that our readers, who may have noticed the discrepancy, may not be placed in any uncertainty in their use of the hydrometeter as an approximate guide.

The assumption upon which the alleged inaccuracy and uselessness of the hydrometer as a test for the printing bath is based, arises out of the consideration that nitrate of soda, or some other base, is formed by double decomposition on the contact between the chloride salt in the paper, and the nitrate of silver solution. This nitrate of soda it is assumed is dissolved out of the paper, and enters into the bath, thus introducing an element which will affect the specific gravity, and nullify any test based thereon. This Mr. Cramb calls one of the "known principles in chemical and hydrostatical science."

Now, it is undoubtedly in accordance with a known principle of chemical science, that when chloride of silver is formed by the double decomposition of nitrate of silver and chloride of sodium, nitrate of soda is also formed; and it is a known fact of hydrostatical science that the introduction of any soluble salt into a fluid affects, in definite ratio, its specific gravity; but it is *not* known to what extent this salt, formed within the fibres of an absorbent fabric, and within the substance of a film of coagulated albumen, will dissolve out into the solution upon which such fabric and such film may be floated for a few minutes. A very few moments intelligent reflection will, however, we think, suggest, under ordinary circumstances, that a portion so inconsiderable as in no way to shake confidence in the hydrometer, as an approximate guide, finds its way into the bath. The first element in arriving at this conclusion, is the fact that, as a rule, the amount of chloride of sodium used is about one-sixth of that of nitrate of silver. So that, to suppose a case, if a quantity of paper which had used up completely ten ounces of solution containing ten grains to the ounce of chloride of sodium, were excited on a silver bath of thirty ounces, the solution would be reduced by this process to twenty ounces; and if the whole of the nitrate of soda formed were dissolved into the bath, and for a rough estimate balancing the extra quantity of nitrate of soda formed by the decomposition of the chloride, which would be about one-third, against its inferior specific gravity to nitrate of silver, which is about one-third, we should have one hundred grains added to the remaining twenty ounces, which would disturb the registration obtained by specific-gravity just five grains in each ounce of solution.

But there are two other considerations which reduce the amount of possible or probable error very considerably. The first is the fact that the nitrate of soda would commence accumulating in the bath from the first, so that some portion would have been carried away in the solution on the surface of every sheet; thus even if, as we have assumed, it had all been dissolved out of the paper, the whole could not have remained in the twenty ounces of solution left, again diminishing the probable ratio of error.

But of more force than any other consideration is, the well-known tendency of soluble salts to remain with the greatest pertinacity in the texture of absorbent substances, such as paper, especially when aided by a film of coagulated albumen. Mr. Cramb informs us that nitrate of silver can permeate the film of coagulated albumen to form the chloride of silver—that of course is a fact never doubted. We have seen a thickness of half an inch of coagulated albumen permeated by nitrate of silver. But Mr. Cramb adds, that "the same *liquid* which *brings* the one *can* and will take the other." Just the whole question in dispute, Mr. Cramb; but to admit that assumption would be to ignore entirely the existence of absorption. How gladly would the photographic printer hail this as a fact; how gladly would he learn that a soluble salt was just as easily and rapidly eliminated from his paper as it is passed into its fibres. But is not Mr. Cramb aware that his print will absorb in ten minutes a quantity of hyposulphite of soda, which twice ten hours of running water will sometimes fail to take away. The same liquid that brought it in, can and will take it out; but it requires many hours and much coaxing to do so. That some portion of the small amount of nitrate of soda will be soaked into the bath, there can be no doubt; but, arguing from analogy, the probable amount passing into the bath during a few minutes floating will be inconsiderably small. That the hydrometer should give, then, sufficiently reliable approximate results for general printing purposes is no violation of "known principles of chemical and hydrostatical science," but in perfect harmony with their wide and intelligent recognition. Let us not be misunderstood, however. There are, doubtless, circumstances when, from the accumulation of the nitrates of soda or ammonia, animal matter, &c., the specific gravity of a solution is not, and cannot be, an entirely reliable guide as to the amount of silver it may contain. To meet such cases comes Mr. Hughes' advice, that the analytical test be used occasionally, once in a week or two, for verification or for ascertaining how far the solution is in a state to allow the hydrometer test to be regarded as indicating, approximately, the strength of the printing solution.

Mr. Cramb will doubtless point to the results of his experiments. It might be quite sufficient to point in answer to those of Mr. Hughes, the accuracy of which we can attest. But those of Mr. Cramb are too contradictory for a satisfactory theory, apart from all other considerations. A special test-bath on which paper was excited sufficient to use four ounces and a half of the solution in one day, was found to register an error of eight grains to the ounce by the hydrometer test. The amount of solution used being again added, and the proper strength made up, the next day five ounces were used, and the hydrometer then gives, with the residue, error to the extent of seventeen grains to the ounce. The third day, the same course being adopted, and four ounces of solution used, when the residue is tested, instead of giving a similar ratio of error, which would have made the deviation twenty-four or twenty-five grains to the ounce, it is only eighteen. Again, we have the results obtained on testing a collodion bath, showing, by the hydrometer test, eight grains to the ounce of solution more than it really contained. What we are to assume from this it is difficult to say: but the first conclusion would be that, ignoring the effect of ether and alcohol, and admitting that the whole of the base of the iodide had been dissolved out of the film into the bath, not less than two ounces of collodion had been excited in every ounce of silver solution. We fear that, with every respect for Mr. Cramb's careful and intelligent experimentalizing, most photographers will be disposed to think that some error of manipulation or calculation must have escaped his attention here and elsewhere.

In conclusion, we may add that the hydrometer test has been in constant use with the most comptetely satisfactory results amongst many of our best printers for many years, and has the sanction of some of our best photographic chemists. Our readers need not fear, therefore, to act on Mr. Hughes' advice: use an analytical test occasionally for exact accuracy, and the hydrometer daily, as a rough, but honest guide.

THE ALBUMEN NEGATIVE PROCESS.

As this process appears just now to be exciting some attention, and, to judge by our correspondence, several of our subscribers appear anxious to give it a trial, we think that a succinct and detailed account of the various manipulations will prove acceptable to those to whom the process is not familiar—to whom the mere statement of formulæ recently given by Mr. Richards may be insufficient.

In a former volume will be found a very full description of an albumen process, by Mr. Negretti; but, as he himself remarks, his method is little suited to amateur use. We shall now select for description a modified process introduced by Mr. Whipple, by which, from its extreme simplicity and certainty, we think the humblest skill may produce good pictures.

1.—Take a pound of lump sugar, and dissolve it in half a pint of clean rain-water, then boil the solution for five minutes, and pour it into a stock-bottle for use.

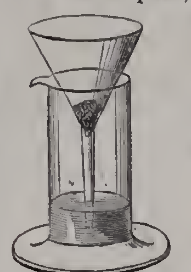
Select always the largest eggs, and as fresh as they can be had. If it is intended to work upon stereoscopic plates, one or two eggs will be quite sufficient to use at a time, as, although the mixture will *generally* keep for a month or more, it sometimes becomes deteriorated much sooner; it is, therefore, advisable not to tax its keeping qualities too severely.

The mixture for coating the plates consists of—

2.—Albumen (one egg)	1 ounce
Syrup (1)	½ ,,
Iodide of potassium	7 grains
Bromide of potassium... ...	3 ,,
Rain-water	1 drachm

The iodide and bromide should first be dissolved in the water, then added to the other ingredients, and the whole placed in a six or eight ounce bottle, which must be shaken vigorously until it is all reduced to a froth. This must be laid aside for at least forty-eight hours, when it should be filtered into a clean bottle, and a small piece of camphor added.

To coat the plate, prepare two small measures, and a funnel that will stand conveniently in them.



Throttle the funnel lightly with a piece of sponge, or wool, and filter through it, into one of the measures, sufficient albumen to cover the plate with. The glass plate, made scrupulously clean, and placed in a pneumatic holder, may now be coated by pouring on the albumen in the same way as collodion, the excess being poured off into the second measure. The first measure must be used exclusively for filtered albumen, by which precaution, all danger from bubbles or dirt may be avoided. The same albumen may be again filtered into the first measure for the next plate, and so on till the whole is used up; or, if all be not required at one time, it may be put back into the bottle for a future occasion.

After draining the albumenized plate about ten or fifteen seconds, it must be laid for a minute upon a levelling stand in order that the film may equalize itself upon the glass: then, holding it at the corners between the finger and thumb, it must be dried over the flame of a spirit lamp, or gas jet, beginning at the corner opposite to that where the albumen was poured off. The plate should be kept, during this operation, constantly moving, that the film may not be burnt, and it must be held slightly inclined so that the excess may drain off from the same corner as before, which must be wiped from time to time upon a piece of clean filtering paper. When the plate is *quite* dry, which may be ascertained by touching lightly the corners, it must be laid aside for a few minutes until it is sufficiently cool to be placed in the bath without jeopardizing the glass—but it is best not to let it get quite cold; when ready, plunge it with one movement into a bath of—

3.—Nitrate of silver	... ...	45 grains
Acetic acid ...	... ...	1 drachm
Distilled water	... ...	1 ounce

The plate should remain in this bath about half a minute, after which it must be well washed with common water. This may be done either with a washing bottle or under a tap, or the plate may be placed in a pan of clean water for a short time, and moved up and down with a horn or silver hook. The object of this washing is to remove the free nitrate of silver from the film, which tends by its presence to promote spontaneous decomposition in the dried plate, and thus injure its keeping qualities, while it does not add to its sensitiveness. It is desirable, therefore, that the whole of it should be removed, so, after a thorough washing, the plate must be placed in a bath or pan of—

4.—Common water	... ...	1 ounce
Chloride ammon.	... ...	2 grains

and left in this solution for at least a minute, that any remaining nitrate of silver may be converted into a chloride.

A thorough washing with common water, to remove the excess of the saline bath, completes the preparation of the plate, which may be left to dry spontaneously, or dried before a fire without flame.

We are not of those who decide upon the merits of a process by the number of plates that can be prepare . by it in given time; but it will be seen that the "albumen" process may vie with most for the simplicity of its formulæ and manipulations.

The time of exposure will, of course, depend upon circumstances, but albumen plates will generally be found to require a rather longer exposure than collodio-albumen. This, however, is a point that the operator can best decide by experiments. Of the two faults, it is better to over-expose than under-expose, as the former may be corrected in developing by using weaker solutions; but the prolonged development necessary to bring out the dark parts of an under-exposed picture is apt to mar the beauty of the half-tints for which this process is so justly celebrated.

The best developer for albumen is without doubt gallic acid: it is also easier of application than either pyrogallic or iron, for its effects are produced more slowly, and the plates, therefore, do not require so much personal attention. Having well cleaned a glass or porcelain pan (gutta-percha will *not* do for this part of the process) with cyanide of potassium, pour into it sufficient just to cover the plate of a saturated solution of gallic acid, which will be found to be nearly—

5.—Gallic acid	... ...	6 grains
Water ...	... ...	1 ounce

to every ounce of this add ten minims of silver solution;

6.—Nitrate silver ...	... ...	5 grains
Water (distilled)	... ...	1 ounce

cover the pan over to exclude dust and light. In about a quarter of an hour the picture will begin to appear, and in two hours or less, according to the amount of exposure, all the details will be visible. If desirable, a little more silver may be added now; but a plate that has had a proper exposure should not need it: in no case should any more silver be added until all the required detail is well out, otherwise the other portions of the picture will exhibit too great a contrast and appear hard.

Should it be found difficult to make the water dissolve the quantity of gallic acid we have named, gentle heat may be used, which will hasten the operation. Indeed, we mentioned the necessary strength of the solution purposely, because persons who are not accustomed to use this salt are apt to mistake the point of saturation. The gallic acid may be employed hot if it be wished to shorten the time of development.

We should notice that a photographic picture upon albumen obstructs chemical light in a much greater degree than one of a similar apparent density upon a collodion film, and therefore the development must be stopped at a point less dense in appearance than would be considered desirable for a collodion negative.

The ordinary pyrogallic acid solution may also be employed with albumen in the usual way, but it is questionable whether the results equal those produced by gallic acid. The strength of the pyrogallic solution should be—

7.—Pyrogallic acid	... ...	1½ grain
Citric acid	... ...	1 "
Distilled water	... ...	1 ounce.

Place the plate on a levelling stand, and thoroughly moisten the surface with clean water. Having drained the plate, pouron the pyrogallic solution, with an addition of five minims of the silver solution (6) to every drachm of developer. In about five minutes the picture will begin to appear. As with gallic acid, no moisture should be added until all the details are quite clear, and only then if really necessary. The solution generally remains clean until the development is complete; but should it discolour much it should be renewed.

The picture must be fixed with hyposulphite of soda in the usual manner. Unless a very large number of positives are required to be printed from it, the negative will not require to be varnished, as the film is very hard, and the picture well in it.

We think the above description will enable any of our readers who may wish to try this process, to do so with success, for it is very uniform in its results when worked with ordinary care. It has at least this advantage, that the *raw material*, albumen, is attainable in its greatest perfection by those who live away from the chief sources of collodion, and to these it may be worth serious attention.

Scientific Gossip.

Some important researches on solar light have recently been communicated by Kirchhoff, to whom, with Bunsen, we already owe so much of our knowledge on this subject. He has succeeded in presenting us with a chemical analysis of the solar atmosphere, by means of an examination of the spectra shown by various chemical substances, and a comparison of these with that of the sun. The author maintains that the sun has an ignited gaseous atmosphere which encloses a core of still higher temperature; and if we could see the spectrum of this atmosphere we should detect the bright lines which are characteristic of the metals existing in it, and should recognise the metals themselves from these. We however see what Kirchhoff calls the *inverted* lines, *i. e.* the lines dark on a luminous field, instead of luminous on a dark field, owing to the body of the sun being of a higher temperature than that of the atmosphere in front of it. A very perfect apparatus was employed, consisting of four large flint-glass prisms, and two telescopes properly mounted. With this the spectra were seen in a hitherto unattainable degree of distinctness and purity. Thousands of lines being exhibited in that of the sun, and those of artificial flames being likewise shown with equal distinctness, provided they were sufficiently luminous. A gas flame was not hot enough, but the sparks from a large Ruhmkorff's induction coil yielded very brilliant spectra of the metals which formed the terminals of the poles. A very simple arrangement permitted the comparison of the spectra of two sources of light. The rays of one of the sources may pass through the upper half of the vertical slit, whilst those of another passes through the lower half. When this is the case, one of the true spectra is seen immediately below the other, and it is easy to see what coincident lines appear in both.

In this manner the author satisfied himself that all the bright lines peculiar to iron correspond to dark lines in the solar spectrum. In the portion of the spectrum between D and F about seventy particularly well defined lines occur, resulting from the iron in the sun's atmosphere. Iron is remarkable on account of the great number of distinct lines which it produces in the solar spectrum; magnesium is interesting, becauso it produces the group of Fraunhofer's lines lying in the green denoted by Fraunhofer by *b*, and consisting of three very strong lines. Very distinct dark lines in the solar spectrum correspond to the bright lines produced by chromium and nickle, and we may, therefore, regard the presence of these substances in the sun's atmosphere as proved. Silver, copper, zinc, lead, aluminium, cobalt, and antimony, have extremely brilliant lines in their spectra; but no distinct dark lines in the solar spectrum correspond to these.

Wonderful accounts having from time to time been published respecting the optical properties of "The Silver Spring" of Florida, the professor of natural philosophy in South Carolina College determined to investigate its properties. As might be expected, the so-called mysterious and wonderful phenomenon which popular report had ascribed to the waters of this spring, were at once seen to be due to well known physical principles; but the account which Professor Le Conte has given of his examinations is so interesting, and the subject—that of the properties of pure water—is so important to all photographers, that we are induced to give a brief abstract of the report which has recently been presented to the American Association for the Advancement of Science. This remarkable spring consists of a basin nearly circular in shape, about 200 feet in diameter, and is surrounded by hills covered with oaks, magnolias, bays, and other gigantic evergreens. The maximum depth of water was found to be not more than 36 feet in the deepest part; the reputed depth was in the neighbourhood stated to be 80 feet; on the borders of the spring this was reduced to 45 feet; whilst in distant parts of the country it was stated at 150 feet; thus affording an illustration of the general law that the accuracy of popular statements bears an inverse proportion to the distance from the point of observation; probably like all emanations from centres, following the law of inverse squares. The most interesting phenomena presented by the spring is the truly extraordinary transparency of the water, in this respect surpassing anything which can be imagined. All the intrinsic beauties which invest it are directly or indirectly referable to its almost perfect diaphaniety. On a clear and calm day, after the sun has obtained sufficient altitude, the view from the side of a small boat floating near the centre of the spring, is beautiful beyond description, and is well calculated to produce a powerful impression upon the imagination. Every feature and configuration of the bottom of this gigantic basin is as distinctly visible as if the water were removed and the atmosphere substituted in its place. A large portion of the bottom of this pool is covered with a luxuriant growth of species of water-grass and gigantic fresh-water algæ, which attain a height of three or four feet. The sunlight illuminates the sides and bottom of this remarkable pool as brilliantly as if nothing obstructed the light. The shadows of the little boat, of the observers' overhanging heads and hats, of projecting crags, &c. of the sorrounding forest, and of the vegetation at the bottom, are distinctly and sharply defined, while the constant waving of the slender and delicate moss-like algæ, by means of the currents in the water, and the swimming of numerous fish above this miniature subaqueous forest, impart a living reality to the scene which can never be forgotton; and if we add to this picture, already sufficiently striking, the fact that objects beneath the surface of the water, when viewed obliquely, are fringed with prismatic hues, we shall cease to wonder at the mysterious pheomena with which vivid imaginations have invested this enchanting spring, as well as at the inaccuracies which have been perpetuated in relation to the wonderful properties of its waters. On a bright day the beholder seems to be looking down from some lofty airy point on a fairy scene in the immense basin beneath him, a scene whose beauty and magical effect is vastly enhanced by the chromatic tints with which it is invested. Numerous comparative experiments were executed in relation to the distances at which cards could be read in air, and at the same distance beneath the surface of the water; the results of which were that when the letters were of considerable size, on a clear and calm day they could be read at about as great a vertical distance beneath the surface of the water as they could be in the atmosphere. The distances were chosen from between six and thirty feet. These results are very remarkable, since Bouguer, in the results of his experiments on the absorption of light by sea-water, estimated that at the depth of 311 French feet the light of the sun would be equal only to that of the full moon, and at the depth of 679 feet would wholly disappear. A redetermination in a more careful manner should, therefore, be made of the transparency of the water of the "silver spring," as the absorption of light by water is a very important subject for photographers as well as scientific persons in general. Should it turn out (as seems most probable) that water in its perfectly pure state is almost as transparent to light as air itself is, there will be no difficulties, other than mechanical ones, in the way of enterprising photographers obtaining pictures of submarine scenery; and from the above description of the clearness of the above spring it is very probable that a water-tight camera lowered down to the bottom, and there connected with suitable apparatus for uncovering and covering the lens, would produce a true subaqueous photograph of the wonderful scenery described. In any experiments of this sort the front surface of the lens should not be allowed to come in contact with the water. The curvatures of the glasses are all calculated on the supposition that the rays of light pass out of a rare medium like air, into the glass. If, instead of air the rays passed direct from the water to the glass, the focus of the combination would be considerably lengthened. This difficulty could be overcome by cementing a piece of plate-glass with parallel sides in front of, and about an inch from the first surface of the lens, which would prevent the water from touching the curved surface of the lens, and as the rays would pass through a *plane* boundary surface of water, instead of a curved one, these errors would be in great measure obviated.

There would still be a difficulty as to the proper focussing of the picture on the ground-glass, which, unless the photographer cared to go down in a diving-bell or diver's dress to the camera, would have to be done at the surface by guess. We have previously heard of a submarine photograph having been taken. If we mistake not, one was spoken of some years ago as having been taken of the bottom of Weymouth harbour; but we are not aware that any detailed account of the way in which this was taken has ever been published.

Notes and Jottings.

Testing Nitrate of Silver Solutions.—Manipulation in the Operating Room.

Some attention has lately been given to the various methods of testing the strength of nitrate of silver solutions. Mr. Hughes, in his paper read at the last meeting of the North London Photographic Association, particularises the several instruments which have been invented for that purpose, but as amateurs may not care to expend even a few shillings in the purchase of one of them, if they can with equal readiness and certainty employ articles which they have in use, we will give the simple method we have been in the habit of adopting.

A stock-bottle of testing solution is always kept in the operating room. It is made thus: pure well-dried chloride of sodium 35 grains; water 100 ounces. One ounce of this solution precipitates as chloride one grain of nitrate of silver. It is therefore evident that any given quantity of silver solution, the strength of which it is required to ascertain, will demand for each grain to the ounce, exactly the same bulk of testing fluid.

Thus, by way of example, let us take a drachm of our printing bath, the strength of which was originally 60 grains to the ounce. Add to it one drop of a saturated solution of bichromate of potash, which should also be kept in stock; we thus obtain orange red chromate of silver, *which loses its colour the moment the full quantity of testing solution is added.* Now add testing solution as long as a precipitate (chloride of silver) falls, or until the silver loses its red tint, the number of drachms so added will exactly equal the number of grains of silver in the solution tested, so that if, say fifty-five drachms be added, each ounce of the nitrate of silver solution will contain fifty-five grains of the latter salt.

The convenience derived from the testing solution being of the strength given, is very great in practice, as it simplifies the calculation very materially. It is by no means needful that even graduated measures should be used; for if we take, say, a wine-glassful of nitrate of silver bath, and find that thirty glassfuls of testing solution will be required to saturate it, then we know that the solution tested contains thirty grains to the ounce.

A short time since we visited the establishment of one of our most eminent photographers, and noticing a few items of manipulation that we thought would interest our readers, we made a jotting of them for their benefit.

The first matter that came under our notice, was a plan for keeping the nitrate of silver bath at an even temperature. To effect this, a water-tight case constructed of wood, having a tap at the bottom, received the gutta-percha bath, leaving a space round it to hold water, which in winter should be warmed, and in summer cooled by ice, so as to bring the temperature to about 60°. The importance of careful attention to see that the bath is neither too hot nor too cold, is a point frequently overlooked even by many professionals, who consequently have to complain of fogging in summer, and dull weak negatives in winter.

Next we observed a simple plan for obtaining a gentle, even stream of water for washing the plate, which the amateur might adopt with considerable advantage in dry plate photography. A length of gutta-percha tubing, pierced with small holes, was fastened to a water-tap, so that a line of small jets spouted on to the plate, placed on a fitting stand. In this position the operator left it to be entirely freed from hypo, while he went on with other matters.

The mixing of the iron and pyrogallic developers lately brought to the notice of the public, had been in use for some time. The method of manipulating differed somewhat from that usually followed. The image was first developed by pyrogallic acid only, and the iron afterwards added to bring out the half tones. Of course, when then the two solutions were mixed, ink was formed; but this did not influence the result. Michael Hannaford.

ON THE PRINCIPLES OF COLLODIO-ALBUMEN PHOTOGRAPHY.

BY THOMAS SEBASTIAN DAVIS.*

In continuation of my report in elucidation of the principles involved in the preparation of dry plates, I have to record the general results of my experiments in connection with the employment of albumen in unison with the excited collodion film. The practical difficulties that have beset the use of such plates, may be described as consisting in a rapid deterioration after preparation, the want of uniform sensibility, liability to blistering, and a general tendency to stains and markings. With regard to the first difficulty, viz., deterioration after preparation, a lengthened experience leads to the inference that free nitrate of silver, in union with albumen, forms a compound prone to decomposition. It becomes, therefore, a question of primary interest to ascertain how far the sensibility of the collodion film can be preserved, without bringing the albumen into collision with free nitrate of silver. To ascertain this point I prepared a plate by covering it with collodion, decomposed the sensitizing salts in the usual nitrate of silver bath, and then washed thoroughly with an abundance of pure water. I then poured over its surface a mixture of dilute albumen, and finally treated it with water at a high temperature (about 200° Fah.) Upon developing the picture, after an exposure of ten minutes, with a Ross's stereo 4½-inch lens, in a fair light, I obtained a result which indicated slight under-exposure. It seemed to me desirable to ascertain in the next place, whether, under similar circumstances to the above, pure iodide of silver be more or less sensitive to the actinic impression than the iodide of silver in combination with the chloride and bromide. In pursuance of the enquiry, I first prepared two samples of collodion, the one I sensitized with iodide of cadmium alone, and the other with a combination of iodide, bromide, and chloride salts. I then prepared two plates with the iodized collodion, and upon removal from the nitrate of silver bath subjected them to a prolonged washing in *pure* water. The one was preserved with my raisin extract preservative solution, and the other with dilute albumen, and each subsequently washed, dried, and exposed. Two other plates were next prepared with the collodion, containing both chlorides and iodides in solution, plunged into a solution of chloride of ammonium, then washed freely with common water, treated respectively with the raisin extract and albumen solution, and lastly washed and dried. It will be noticed by the above treatment we obtain two films containing iodide of silver, and two others, in which the iodide is in intimate admixture with the chloride. In comparing the relative sensibilities of two photographic surfaces to the action of light, I have found it necessary to expose them simultaneously, otherwise the variation in the actinic intensity within a few minutes is calculated to lead to false inferences. To avoid any source of error from this cause, I exposed the plates, prepared as above, in two cameras fitted with corresponding lenses, and found on development that under the above-mentioned circumstances the iodide of silver, plus chloride of silver, gives evidences of possessing a greater sensibility than iodide of silver minus the chloride. The relative difference may be estimated ar three is to four in respect to the plates prepared with the raisin extract, and as two to three between the two prepared with the diluted albumen. The above experiments indicate, however, that the collodio-albumen plates can be preserved in a sufficiently sensitive condition for general landscape purposes, without the conversion of the albumen into the compound that is recognised (whether correctly or not) by photographers as the albuminate of silver. It seems, however, desirable to ascertain the proportionate sensibility between a plate prepared with or without the formation of the albumino-nitrate of silver compound. Perhaps the most sensitive surface that can be produced of this character is by following the Taupenot process, and using the second bath in a neutral state. Although

* In continuation of the Report of the Experimental Committee of the South London Photographic Society upon the Dry Processes.

the plate in this condition is exceedingly deficient of keeping qualifications, it yet possesses considerable sensibility. The result of some comparative observations upon the subject, lead to the inference that Taupenot plates so prepared have about twice the average sensibility of those containing a combination of iodide and chloride of silver, and preserved with plain albumen. I do not find that any increased sensibility is attainable in the latter instance by treating the washed albumenized plate with a solution of gallic acid. I am inclined to deduce as a general inference, from varied experiments on the subject, that a layer of albumen intervening between the silver salts and the excited collodion film, or the presence of insensitive salts upon or within its interstices, are directly antagonistic to photographic action. Without having recourse therefore to any theoretical speculations with regard to physical modifications of structure, we are enabled to explain satisfactorily the principles on which the various modifications that have been successfully applied in connection with collodio-albumen photography depend for their practical value. It will be noticed throughout that in those cases in which the albumen does not contain iodides, it need not be brought into contact with the nitrate of silver solution, but that it becomes advisable, as noticed by Mr. Fothergill, to remove from the surface of the film the greater portion of the insensitive coating. If the albumen has become dessicated, or partially so, by spontaneous evaporation, it will be found more efficacious to use hot than cold water to effect its removal. The superior efficiency of the former will be apparent if we coat a piece of glass with liquid albumen, dry it at a high temperature (say 200° Fah.) then attempt to wash it from the surface of the glass by the aid of cold or boiling water. It will be noticed that although the layer of albumen resting simply upon the surface of the glass is not coagulated by the heat applied, it has been rendered less easily soluble in cold water. If moreover we dip the glass covered with the thin film into boiling water, we shall not find that any opacity is produced indicative of a structural alteration in its character. Although I am inclined to the belief that the same reasoning would apply to a layer of albumen resting upon the surface of the collodion film, yet we do not possess any demonstrative experiments to show that it would equally be applicable to the portion retained within the interstices of the film, in intimate proximity with the metallic salts. At all events it is to be observed that those experiments which have been adduced in favour of increased sensibility attributed to structural alteration, are explicable upon the simple principle of a removal of the insensitive or even antagonistic influence of the preservative agent. Regarded in the light of the theory advocated, in conjunction with the fact of the possibility of preserving the sensibility of the collodio-albumen compound, without the necessity of bringing the albumen in contact with free nitrate of silver, as shown by my experiments, we can easily understand the unity of principle existing between the preparation of plates by the Fothergill, Petschler, and other published methods of manipulation.

I have now, in conclusion, to offer an opinion with reference to the best practical method of preparation; or in other words, the one which offers the greatest number of general advantages as a dry plate process. As the preference must be made in subordination to special requirements, it is advisable to state that the leading qualifications which I consider a dry plate process ought to possess are these, facility and readiness of obtaining uniformity of preparation, moderate sensibility, certainty of results, one sensitizing bath, and considerable keeping qualities. I am inclined to think that the great care that would be required to preserve plates in an unimpaired condition, the lengthened period of exposure during preparation and development, the necessity for the avoidance of any contact with deleterious vapours would militate against the utility of dry plates possessing equal sensibility with ordinary wet ones, when required for general landscape delineation. In those cases in which a greater sensibility than one half or third of that of wet collodion be requisite, the balance of advantages will in all probability remain in favour of the wet or preservative process.

In subjection to the above considerations and experiments, and to meet the exigencies of ordinary landscape or still-life photography, I have devised, and would generally recommend the following collodio-albumen dry process.

Take six fluid drachms of any good negative collodion of a non-contractile character, and add thereto two drachms of the following sensitizing solution;—

Iodide of potassium	8 grains
Iodide of cadmium	16 grains
Bromide of ammonium	2 grains
Chloride of ammonium	1 grains
Alcohol ·805	6 fluid drachms

Digest for three or four hours with occasional agitation, carefully filter, and add two additional drachms of alcohol so as to make up to one fluid ounce. Sensitize the plate in the ordinary 35-grain neutral nitrate solution, immerse in a dish of (pure) water, to which has been previously added a drachm or two of a five per cent. solution of chloride of ammonium, remove and wash thoroughly with ordinary filtered water. The plate is then to be covered with the following preservative solution:—

Raisin extract solution (Raisins 1 fluid drachm, water 5 fluid drachms)	1 ounce.
Albumen	1 ,,
Ammonia	10 minims.

Agitate the whole together in a large bottle, and filter through sponge just before using.

The first quantity applied should be made to flow over the plate in a continuous wave, and be poured off at once from the opposite corner; the second be permitted to remain thereupon not less than a minute. The plate is now to be washed freely with filtered water applied from a jug, or other convenient manner, then stood on end to dry spontaneously, or by the application of a gentle heat, and is ready for use. After exposure the dry plate should be moistened with distilled water, and developed with the following solution:—

Pyrogallic acid	1½ grains
Citric acid	½ grain
Water	1 fluid ounce
(Alcohol	10 minims

Add to each fluid ounce about half a drachm of a 15-grain solution of nitrate of silver. Fix with hyposulphite of soda, wash, spontaneously dry, warm, and varnish as usual.

February 13th, 1861.

Photographic Tourist.

PHOTOGRAPHY IN JAVA.*

ACCOUNT OF A SHORT PHOTOGRAPHIC RAMBLE THROUGH THE INTERIOR OF THE EAST END OF THE ISLAND.

We had now been staying four days at Paree, during which time we had photographed all of interest in the neighbourhood, and it was then our intention to have proceeded to Ngantang, but the controleur, (a Government official, whose duty it was to examine all the coffee lands belonging to Government), having arrived, we determined to stay a few days longer, and accompany him in his inspections in the district, giving us a chance of seeing a deal of the surrounding country.

We also had an opportunity of seeing the reverence Government officials are held in by the poorer classes of the Javenese, as in riding along the roads all the coolies kneel on the ground, and hold their hands in a praying position until he has passed, even the chief of the place (who with strangers quite affects European manners), sits only on the ground in his presence.

Some years ago the district had its own controleur, who met with his death in an extraordinary manner, the circumstances of which I will relate as told to me by the Javanese. I must first state how we came to hear of it.

We had been told of some ruined tomb at a short distance (which we wished to see whether worth photographing or not), adjoining which was a shed containing a box of clothes, supposed to have been worn by the chiefs of the place some 700 years ago; these being held in great reverence by the natives, having always a guard of five men, who, at their death, are replaced, we were naturally anxious to see the place at all events; but on asking assistance from the chief, he, to prevent our going, told us that if we were decided on seeing it we could, but that we should be certain to get into trouble, as no European had ever been there without subsequent misfortune. As an instance, they cited

* Continued from p. 79.

the case of the controleur before mentioned, who, regardless of the Javanese superstitions, entered the place, and dressed himself in the garments; the consequence of which, they say, was that he could not go from home afterwards without meeting a tiger; and on going a journey one day to Kedirie, on passing the jungle mentioned at the commencement of this journal, a tiger sprang on to his carriage, and, without harming, so affected him with fright, that he died shortly after returning home Many of the European residents verify the fact of his meeting the tiger and his subsequent death, and also say, that if we had persisted in visiting the place, and had not met with misfortune, that they (the Javanese) would have brought it on to us by producing dysentry, or other sickness, which they are very expert at, merely for the sake of verifying their prophecies. But the Government of Dutch India wisely do not allow these superstitions to be interfered with even by their own officials.

The controleur having left, in the evening we proceeded to pack up our things, but on examining the chemicals found the cyanide of potassium was missing; this was rather annoying, as we were upwards of a hundred miles from where we could procure more, and we were doubtful whether any pictures taken in the meantime, and not fixed, would keep until we could get another supply, which would at least take a week, as one of us was obliged to go on horseback to the seaport of Pasoeroan, where we had a relay of materials, and from which a stranger would not have been able to select the right one; the only explanation of its loss was that some of the men about the place had heard of its poisonous properties, and thought it might be made useful; we offered a reward of fifty rupees, but without effect.

During our stay at Paree our table consisted of several strange dishes,—peacock steaks, very much resembling veal; a kind of fat caterpillar found in the rattan, which, though rather offensive to the sight, are very delicious, and considered the greatest delicacy by the Javanese; the legs of a large species of bat, measuring five feet across the wings; and above all the young shoots of the rattan which, forming as it does in England, an important addition to the dress of ladies, here makes us an excellent substitute for asparagus, which in taste and appearance it closely resembles, of other vegetables we had none, rice generally taking their place.

On the following day, after the departure of the controleur, we started off twenty-seven coolies with our apparatus, wearing apparel, a case of wine, and one of provisions, as we intended to stay some time at Ngantang, our destination, and every one requiring so many clothes in a hot climate makes the baggage rather heavy.

After riding on the road a few miles we came upon a splendid banyan tree, stretching its roots over a large surface of ground, but as usual without being able to get a single point of view, owing to its immense size; we, therefore, rode on to our intended destination for the night, a small village which had also its place of accommodation for travellers; but the people being taken by surprise, not expecting anybody, shut themselves in their houses, and gave out that they were all away. It being by this time rather late in the day, and having as yet had nothing to eat, we all felt rather peckish, but could get nothing from them; but having, luckily, with us a peacock, shot the previous day, and having taken possession of the pasangrahan, we set to work to grill part of it, what with this, a tin of "pate de fois gras," one of biscuits, and a bottle of wine, and the assistance of a Chinese opium seller in the neighbourhood, who sent us cakes, oranges, and tea, we did not fare so badly; so after giving our horses grass which we ordered our coolies to cut, we determined to push on to Ngantang (about 11 miles further) that night, as there was no chance of our getting sleeping accommodation where we were.

As the road had (from our starting-place) hitherto been through a flat country, and now commencing to mount the hills, we found the atmosphere cooler at every step, as we had to follow the mountain ridges sometimes falling 300 feet on each side, the views around us were truly grand.

At every turning something new would burst upon us, some distant stretch of country, or lovely vale; mountain ferns also made their appearance, never seen in the lowlands; after mounting hill after hill, to the height of perhaps 3,000 feet above the sea, we commenced gradually to descend, the road at last opening out into a long valley, at the other end of which lay our destination; our horses were by this time nearly done up, the continual ascent having been too much for them, after previously coming such a distance; an English horse would, perhaps, go twice as far without giving in, but here the horses are not larger than an English pony, making them, of course not able to endure near the same fatigue.

By the time we arrived we were nearly as wearied as our horses, having been exposed to the sun ever since early morning, and were very glad to rest ourselves.

Ngantang is about one of the prettiest situated places in Java, being shut in on three sides by mountain ranges, the volcanic mountain Kloet rising in front to a great height, rice fields and cocoa-nut plantations reaching to its foot.

Lying, as Ngantang does, some 1,700 feet above the level of the sea, the climate is very agreeable, at night being so cold as to require two or three blankets, though in the middle of the day, and in the direct rays of the sun, being nearly as hot as in a lower district.

The pasangrahan, unlike the one at Paree (which having been the residence of a European was built of stone) was in the true Javanese style, built of matting, and roofed with jungle grass, having a room built in front open at all sides, for use during the day.

Having arranged all things satisfactorily for our comfort, our first few days were spent in taking walks and rides in the neighbourhood, selecting the best views so as to lose no time in our operations when we should receive the cyanide.

Living, as we now had to do, far from European society, and having none but Javanese to talk to, the time passed rather monotonously, also our having so many nice views in the neighbourhood, and our not being able to take them, several within a short distance of the house we tried, instantly transferring them to a dark place to be fixed at a future time, but with the uncertainty as to whether they would remain unchanged, as we did not care to take our materials any distance, for fear that our labours might all be lost.

After eight days of impatience the cyanide arrived, and we proceeded in the first place to fix what few views we had taken, the cyanide acting as usual, though leaving a peculiar film slightly obscuring the transparency of the blacks, not, however, in any way affecting the picture as a negative

(*To be continued.*)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 20th February, 1861.

There is a very ingenious method of gaining fame or notoriety, frequently resorted to by photographers, whose vanity overcomes every consideration of truth and honour. They find that by announcing the successful attainment (in their hands) of some desideratum in the art, which shall completely remove a host of difficulties that now beset the operator, or accomplish some marvel hitherto deemed hopeless or impossible, they achieve as much greatness as if they had really made the discovery.

Among the most notorious instances of this mode of cheating fame was that of the American, Hill, who unblushingly announced to the world that he had discovered the secret of photographing in natural colours. Of course, we had, for a time to believe the bold assertion, and Mr. Hill succeeded in gaining an extensive share of newspaper notoriety. But as for the promised secret, we have waited long enough for it, so long, indeed, that in the interim Mr.

Hill has sunk into his original obscurity, and earned well-merited contempt for his barefaced imposture. Other instances will doubtless occur to you, in which golden visions were raised of "unfading positives," "proofs without salts of silver," &c., &c., which, of course, have never been realized; but they have served the purpose of raising their proposers into temporary notoriety, and thus far, at least, have satisfied their object. With these *fiascos* in view, we naturally receive with caution and suspicion any announcement of wonderful results unaccompanied with ocular proofs. At the last meeting of our Photographic Society a member announced that he had discovered a process, which, as he *said*, was calculated to effect a considerable modification in the photographic processes now in vogue. He did not explain the nature of the modification, nor by what means he had been led to his discovery; he "wishes to perfect it before giving it to the world;" meanwhile, it has leaked out, that this discovery consists in obtaining direct positives on paper in the camera, with the "whites" and "blacks" of irreproachable purity. This, if my memory does not deceive me, is not the first time such a result has been announced as a *fait accompli*. I do not question its realization in the present instance, on the contrary, I would rather believe it than not; but, as I said before, experience prompts caution, and a disposition to believe only in ocular proof.

The solar camera continues to engage the attention of the scientific inquirer; and very elaborate discussions have taken place in our society both on the soundness of the principles upon which this instrument is constructed, and on the means by which it may be still further improved. The question has been greatly simplified by the observations of Mr. Leon Foucault; and I think that there ought now to be no difficulty in constructing a solar camera that shall fully realize all that has been expected or required of it.

I have seen no detailed description in the English journals of the American *Telesmatic* apparatus invented by Mr. Fontayne, which prints one thousand proofs or more an hour. A full account of this marvellous invention, upon which, it must be confessed, the world was somewhat sceptical, has recently come under my notice; and as I think it will be no less interesting to you than it has proved to us, I give you a summary of its principal features. The mechanism of the apparatus is extremely simple, and acts with as much precision as that of astronomical apparatus. In one hour 4,000 positives on paper can be printed from one negative, each measuring about an inch square. The paper upon which they are printed, as you may suppose, is not prepared with chloride of silver: the time of exposure is so short, that this salt does not offer sufficient sensibility: ordinary paper is sized with gelatine mixed with iodide of silver and other sensitive salts intended to produce a highly sensitive surface. This paper is rolled upon a cylinder, similarly arranged to that in the printing electric telegraph, which, set in motion by clockwork, unrolls itself slowly and regularly: the whole is contained within a dark box furnished with a single aperture. The negative slides within this aperture, and the sensitive paper is so arranged beneath it, that for a definite, but very brief period, it touches the negative. The mechanical apparatus is also so constructed, that the paper remains for about a second in contact with the negative, and at the same time, by an equally rapid motion, it opens and shuts a cap placed over the negative; while over the cap a condensing lens is placed, which throws the concentrated rays of the sun on the negative, and, consequently, on to the sensitive paper.

The complete action of the machine, you will perceive, is accomplished in the short space of a second of time: during which the paper is brought into contact with the negative, the cap opens, the paper remaining exposed to the light for about a second, and the cap is closed; again the paper moves, the impressed portion travels on, and a fresh portion of paper comes under the negative, to be impressed in its turn. By accelerating the motion of the machine, this action may be repeated one hundred times a minute, or six thousand times in an hour.

From 200 to 250 proofs are printed on each sheet of paper; they are removed to the dark room, and developed in the usual manner, with gallic acid, acetic acid, and nitrate of silver; and afterwards fixed in hyposulphite of soda. Thus, without exhibiting anything precisely new, this machine comprises a happy combination of the best means for securing the desired result, and when confidence in its power becomes established, it will doubtless come into extensive operation.

Mr. Retzinski gives the following description of his method of printing positives, which, from its economy, he considers worthy the attention of amateurs, who are generally so wasteful with their salts of silver.

To 35 ounces of albumen add 45 grains of chloride of sodium, heat into a froth, and allow it to subside for four-and-twenty hours, then filter in the usual manner.

The paper must be floated on the albumen for six minutes, when dry, sensitise on a silver solution of the strength of five per cent., or 22 grains of silver crystals to the ounce of water.

This bath may appear to be very weak, as the strength usually recommended is 20 per cent. But Mr. Retzinski thinks that he effects a gain of 75 per cent. of silver, with no disadvantage, except that the proofs require longer exposure in the printing frame.

The paper is floated on the silver solution forty-five seconds, and not longer. It is afterwards printed, fixed, and toned in the usual manner.

If you do not find much novelty in Mr. Retzinski's formulæ, it may be considered valuable for its economical suggestions, as the tendency among operators has of late ran into excessively strong silver solutions, which renders printing in the hands of amateurs a very costly business.

The proposal to adjourn the awarding of the De Luynes' prize of 8,000 francs for a successful method of converting photographic proofs into plates from which any number of proofs might be taken, either by lithography or the other methods of printing engravings, until the 1st of April, 1864, has been adopted by the committee. It is hoped that the additional time given to competitors will lead to a satisfactory solution of this most important photographic problem.

Among the conditions, exhibitors at our next Photographic Exhibition must comply with, I omitted to state, that the pictures sent must be accompanied by their title, the process by which they are taken, and the exhibitor's name and address; the price, if for sale, cannot be allowed to be affixed to the frames, but must be communicated to the secretary in the note of particulars accompanying the pictures. During the Exhibition no pictures can be removed from it but after it is closed they must be removed within eight days.

Proceedings of Societies.

Birmingham Photographic Society.

The ordinary monthly meeting of this society was held on the 29th of January, Mr. W. B. Osborn in the chair.

The discussion upon Mr. Rejlander's paper being resumed,

Mr. Turner said he had worked for six or seven years, but had never seen the scum on the bath until within the last six months, when, in consequence of the coldness of the weather, he had had a stove erected in his room. Since that had been put up, owing, he supposed, to the fumes of sulphur generated by it, he had frequently detected the scum. He believed that almost all the difficulties that photographers had to contend with were attributable to want of cleanliness. He made a point of filtering his bath every night, by means of a contrivance he found very useful. It consisted of a funnel fitted into a glass jar, a plug of cotton wool being inserted in the tube of the funnel. This effectually filtered the bath. On each side of the jar also was a tube on the syphon principle, and, by blowing through one, the bath could be filtered by means of the other, without disturbing the sediment that might have collected. He believed also that the want of care in cleaning the glasses was a very fruitful cause of this scum forming. He generally cleaned his glasses on both sides with nitric acid and water.

The Chairman said he had often observed that amateur photographers considered it quite sufficient to clean one side of the glass only, a prolific source of danger to the bath.

Mr. Turner said that at the last meeting Mr. Rejlander left two glass plates, which he complained of as resisting all efforts to clean them. He (Mr. Turner) cleaned one with nitric acid and water, and took a portrait of the Honorary Secretary upon it. Mr. Hart, he added, had cleaned the other with levigated emery and water, and had taken a picture upon it. The plates were now quite clean, and free from any markings.

Mr. Breese said, that in looking over some negatives a few days since, he found six which had cracked all over, and upon examining them he perceived that they were all upon *white* glass, while those taken upon glass with a green tinge had remained perfect. He was of opinion that the white glass absorbed moisture from the atmosphere, and acting upon the porous collodion film imprisoned under the hard varnish, caused it to swell, and finally to crack the varnish. He was borne out, he thought, in this opinion, by the fact that he had one negative kept in the same box (which was on white glass, but unvarnished) which had remained perfect.

The Chairman observed that he could endorse the last speaker's opinion, as he had frequently noticed this defect—vulgarly called "sweating"—in colourless or white glass.

Mr. Turner had used the colourless plate, and never found this defect.

Mr. Plante said his practice was, previous to varnishing the negative, to clean off a narrow rim all round the glass; then to warm it and pour the varnish all over it. By this means moisture was prevented from creeping under the film; and yet with all these precautions he had frequently found the films on the colourless glass, which films from lapse of time were split all over. He had also negatives which, quite clean when done, were now marbled all over, probably from the same cause. He found the best method of cleansing glass plates was to place them upright in a solution of one part sulphuric acid, four parts water, and after some hours to neutralise the acid with best chalk. This process covered the glasses with a very fine deposit of chalk, which, when rubbed off, gave a brilliant surface to the glass.

After some further conversation on the subject,

A number of choice photographs were displayed, as the presentation prints, the allotment being—one large print, two small ones, or six stereographs for each member. The Secretary then announced that Mr. Robinson, of Leamington, had, with great liberality forwarded one of his photographs for presentation to each member of the society.

After the usual votes of thanks the proceedings terminated.

Manchester Photographic Society.

The monthly meeting of this society was held on the 6th inst., Mr. Wardley in the chair.

Some correspondence was read in reference to the approaching meeting of the British Association. The Secretary, Mr. Mudd, Mr. Neild, and Mr. Sidebotham were appointed representatives.

A conversation on the panoramic and other lenses ensued.

The Chairman observed that much had been said lately about the centring of lenses; but the error that was likely to occur was of very little moment in those for landscape purposes. The subject of lenses being before the meeting, he wished to call attention to the importance of devising some method of expressing the capabilities of the various combinations now before the public, as compared with the ordinary landscape objective. The practice of measuring the focus from the back lens of a compound portrait, triplet, or orthographic, was erroneous in principle; consequently photographers, unacquainted with this fact, were liable to be led astray when they hear of a 3½-inch focus lens (compound form) covering a circle of nearly five inches. Upon trying a lens of this character, they would find the size of image and circle of good definition, equivalent to an ordinary meniscus of about 4½ inches focus. It would be much beter if the compound lenses were expressed in equivalents with our old landscape lenses.

[The practice which prevails amongst opticians, and of which Mr. Wardley complains, is certainly a delusive one. It has arisen, we believe, simply out of trade exigencies, and not from any desire to deceive. It has become a habit to state the focus from the back lens of a combination to guide the camera-maker as to the length of body required. If the equivalent focus were given to him as a guide, he would very probably make a camera in which the ground glass could not be brought near enough to the lens by an inch or two. We were once absolutely served so. Mr. Dallmeyer's new stereo lens, described as of 3½ inches focus, is about 5 inches equivalent focus. The best plan in describing a lens would be to state both equivalent focus, and focus from the back lens. No mistake could then occur.—Ed.]

City of Glasgow and West of Scotland Photographic Society.

The ordinary monthly meeting of this society was held on the 7th inst., J. Kibble, Esq., presiding.

Mr. Stuart showed some prints, produced by a photo-lithographic process, which he would not then disclose, but stated that it was different from any yet published.

Mr. John Cramb then read a paper "On the Testing of Used Silver Baths, and the Hydrometer Silver Meter."

After some preliminary observations on the subject, he described the method of testing silver solutions as follows:—"Having accurately weighed out 60 grains of pure dried chloride of sodium, dissolve in 170 drachms of distilled water. A bottle which is known to hold this quantity is a more convenient and also more correct method than a large measure with a great surface, which renders it difficult to observe the exact amount. Measure a drachm of the silver solution to be tested. Render acid by nitric acid. Put this into say a two-ounce phial, wash out the measure with distilled water, and add the washings to the silver solution. If you are sure there must be say 20 grains to the ounce of silver solution, add at once as much of the chloride solution as will precipitate the amount of silver. Then add carefully, little by little, shaking each time you add chloride. Observe how much chloride you have used before you again add a quantity. At a certain point precipitation will cease: you may add more chloride to make certain. But the quantity of chloride used *before* the point at which you observed there was no more precipitation is the quantity you found your calculation upon. Suppose a case, and say it required *three* drachms of solution of chloride of sodium to precipitate all the silver from the *one* drachm of solution operated on, proving that there were *three* grains of nitrate of silver present in the drachm of the bath tested, or equal to *twenty-four* grains of nitrate of silver to the ounce of solution." He then proceeded to state his conviction that the hydrometer was useless as a test for either collodion baths or printing solutions. "An old collodion bath might contain substances which would make it lighter than water—namely, alcohol or ether, or substances which would make it heavier, such as the nitrate of potash, cadmium, or ammonium, &c., or redissolved cotton, &c. In the printing bath there is no such disturbing cause. The error in using the hydrometer is always in one direction. The bath steadily, the longer it is used, acquires the more of heavy matter—nitrate of soda or ammonia." He then proceeded to comment on a recent paper read by Mr. Hughes at the meeting of the North London Photographic Society, and on the experiments illustrating it, adding that such experiments were "complete befooling," as the results were, he considered, unsatisfactory and contradictory.

In the course of his paper Mr. Cramb gave the results of some experiments as follows:—

	Grains of Silver per ounce as shown by	
	Hydrometer Tester	Analytical Test
Collodion bath from Mr. John Urie	29	29
" " Mr. A. Macnab	31	34
" " Mr. J. Bowman	33	25
" " Cramb Brothers, No. 1	26	28
" " " No. 2	31	33
Albumenized paper printing bath from Mr. J. Stuart ...	96	84
" " " Mr. A. Robertson	68	63
" " " Mr. H. M'Farlane	105	88
" " " Mr. D. Brown ...	100	94
Very old ditto from Cramb Brothers	56	31
Special test baths, from Cramb Brothers—		
A new bath for printing, made to 90 grains, 8 ounces of solution, used one day, and reduced to 4½ ounces of solution	70	62
The same bath, again made up to 90 grs., 8 ounces of solution, used one day, and reduced to 3 ounces of solution	62	45
The same, again made up to 90 grains, 8 ounces of solution, used one day, and reduced to 4 ounces of solution ...	66	48
A new 60-grain printing bath, 8 ounces of solution, used one day, and reduced to 4½ ounces of solution	41	32
The same bath, made up to 60 grains, 8 ounces of solution, used one day, and reduced to 5 ounces of solution ...	56	44

At the conclusion of the paper Mr. James Cramb performed some of the experiments in the presence of the meeting. After which a conversational discussion ensued on the use of the hydrometer; the unfortunate instrument being alternately denounced as a toy and a cheat. After some votes of thanks the meeting was adjourned to the following week, when the discussion and experiments were to be resumed.

Photographic Notes and Queries.

EXPOSURE FOR DRY PLATES.

SIR,—I have several times been on the point of addressing you upon a subject which has a good deal embarrassed me. I allude to the marvellously short exposures recommended, both orally and by "the books," for plates prepared by the dry process. Five, ten, and thirty seconds have been prescribed, while I, and many like me, using the best materials, are compelled to give as many minutes. Some time back (in concert with a clerical friend who was equally puzzled) I contrived a plan which we thought would afford a fair test of the value of various exposures. We arranged our camera so that about three-quarters of an inch of the plate was exposed each time, thus reproducing the picture at short intervals on its whole length. We commenced with half a minute—going "minutely" to work—though considering a little excess of exposure a matter of slight moment, we thought that a little more or less was of secondary importance. We increased half-a-minute—a minute, two, four, up to fifteen, and, *cæteris paribus*, we decided that four and a half minutes' exposure gave the best picture. In this opinion we were confirmed by the authority of professional men who saw the print. I should add that this was taken with a Jamin quarter-plate lens, stopped to about half an inch, and in sunshine.

I have noticed, at the present Exhibition, a frame of Fothergill prints, in which the mode of manipulation is given; and among other information we are told that the time of exposure was from *five* to *ten seconds.* I would make the remark with all humility; but if the author wished to impress us with the total inadequacy of a short exposure, he has, to my mind, entirely succeeded. I beg to enclose two prints, taken by the Fothergill process in the fall of last year. To the one (the oak) I gave fifteen minutes; to the other (the ash) I gave half an hour's exposure. The day was bright in the one case—somewhat lowering in the other. The defect which your critical eye will readily detect in the latter arose from a blunder in placing the film side upon the holder before developing. I send the prints to you as they came, like Venus, from the "bath," and like her, without any adornment beyond that "laid by the cunning hand of nature only." There is no manipulating of the skies, nor any of those "aids to development" common among the professors of the art. I am aware that my prints are a long way off perfection; I am also aware that comparisons are odious; but I hope you won't accuse me of vanity, if I ask you whether they might not be placed in juxtaposition to those I have referred to, and not be greatly injured by the operation.

If you think so, I shall be encouraged to persevere in the course I have adopted, and when my short-exposing friends proffer their advice, to give them what their system has never given me, a decided "negative." I am, sir, your obedient servant, H. T. T.

5, *February*, 1861.

[The common fault of most dry plate negatives is under-exposure. These produce hard pictures, with snowy, patchy lights, and photographers are then led to regret that it is the tendency of dry plates to give these results. We believe it is simply the tendency of photographers to under-expose and over-develop, and that with proper treatment the results may frequently equal wet collodion. Witness the specimens of Mudd, Lyte, Wardley, Bourne, and others in the present Exhibition. Your specimens are very respectable, and infinitely better than if they had been exposed a shorter time.—ED.]

SOLAR THEORY.

London, Feb. 19th, 1861.

DEAR SIR,—Having read, with great interest, the accounts in the PHOTOGRAPHIC NEWS, given by the various observers, concerning the phenomena connected with the late Solar Eclipse, with your kind permission I will endeavour to give my ideas concerning the protuberances and roseate matter seen on the sun's surface.

It is known that the light received by us from the sun does not include rays of every degree of refrangibility, but that the solar spectrum, as seen through a telescope, is crossed by nearly 600 dark lines, indicating the absence of certain rays.

Sir D. Brewster discovered that artificial light, which commonly contains no such lines, by passing through a small thickness of nitrous acid, is made to exhibit them; and it is a curious fact, that the nitrous acid absorbs exactly those rays of definite refrangibilities which are missing in sunlight, and the sunlight being passed through nitrous acid, the lines become wider until they run into one another, therefore NO_3, of a certain thickness, will (I presume) absorb all the rays of every degree of refrangibility.

It is proved that the sun is covered to the height of 8″ or 10″ with a roseate matter. Now, sir, might not that matter and the protuberances be composed of NO_3?

I have not the chemical knowledge to be able to say whether NO_3 would be decomposed into its elements O and N by the intense heat at the surface of the sun, or whether a mixture the same as atmospheric air may be made to combine to form nitrous acid from the same cause; that I leave for persons abler than myself to decide.

The sun and earth (according to the nebular hypothesis put forth by Laplace) was formed by condensation, is it not possible that N and O may exist on the sun's surface as well as on the earth?

Might not the so-called temporary stars arise from their being surrounded to a great thickness by the same matter, and their bursting forth in the manner they do be caused by their being seen through openings in the mass of cloud, caused by some disturbance from beneath the surface; and the sudden disappearance of some from the heavens, I think, may be accounted for by the supposition that large masses of nitrous vapour revolving round the star as a planet, and interposing between us and the luminary, it may be years before it would have passed the star so as to allow it to become visible again; its volume may be many times larger than the star, and travel comparatively slow. Hoping that I have not occupied too much of your valuable time, I remain yours respectfully,

CHARLES G. SHONE.

P.S. Perhaps some of your correspondents would favour me with their ideas upon the subject.—C. G. S.

WARMING THE STUDIO.

DEAR SIR.—I wish to devise some economical means of heating my studio and operating room, a heat of 60° at the least, being required in the latter. The length is 24 ft.×9 ft. Could some of your readers assist me in this matter? Yours &c. TYRO.

P.S.—The room is built of wood covered with felt.

ALBUMENIZED PAPER AND ALKALINE TONING.

SIR,—It is with considerable interest and satisfaction I weekly peruse my NEWS; but I must confess myself somewhat surprised at the difficulties which some of your correspondents appear to encounter with respect to albumenized paper and alkaline toning. Herewith are two pictures taken at random from yesterday's batch:—Silver bath, 60 grains; float, 3 minutes; after printing, wash well; tone in gold, 2 grains; water, 1 pint (slightly warmed), and carbonate of soda, 4 grains; fix in saturated solution of hypo. I have a juvenile to excite my paper, and, under my superintendence, to tone and fix. The paper I use and prefer is that of a Hammersmith maker, advertised in your journal.

I should state, *par parentheses*, the above solution tones two whole sheets of paper. And now for "the causes of failure:"—this appears to me to reduce itself to two small proportions; firstly, *allowing the silver bath to become weak;* secondly, *a too liberal use of carbonate of soda.* I do think, sir, if some of your correspondents were to try my plan, *especially attending to the silver bath*, the paper, and the soda, as *perhaps* a secondary consideration, they will no further have cause to complain.

Enclosing my card for your satisfaction, I am, sir, yours obediently, PHOS.

[The prints enclosed are perfectly satisfactory. Personally our experience confirms that of our Correspondent.—ED.]

Talk in the Studio.

Royal Portraits.—Mr. Mayall had been engaged during the last few days, at Buckingham Palace, in taking a new series of photographic portraits of the Queen and Royal family. The series published last summer acquired a popularity so great, that for some time past the negatives have been inadequate to the production of more than a percentage upon the demand. This had led to the issue of pirated copies of the originals, which are at once libels upon the art, the artist, and the royal originals. This piracy is an evil of the most irritating nature to the first-class photographer, as he is, by it, not only injured in purse, but in reputation, by the spurious copies being regarded as his work. We regret to say it is a species of dishonesty that some respectable houses have not hesitated to adopt. We noticed, the other day, in passing the establishment of a respectable house, and one, which, if we mistake not, has made heavy complaints of the piracies of photographs issued by it, a whole series of card portraits which, from the want of sharpness, and the peculiar texture or grain which pervaded the prints, bore unmistakable traces of being copies. In regard to the royal portraits, in the face of it being impossible to meet the supply at a legitimate price, we have heard that they have been offered to "the trade" as low as three shillings a dozen, a price which would at once indicate their quality and origin. Mr. Mayall has, we understand, notwithstanding the imperfection of the copyright law, been able to adopt, in regard to the series now in preparation, a plan which will enable him at once to detect and punish piracy.

South London Photographic Society.—The usual monthly meeting of this society was held in St. Peter's School Room, Walworth Road. The subjects which were to occupy attention consisted in the resumption of adjourned discussion on Celestial and Meteorological Photography; the continuation of the Report of the Experimental Committee (see p. 90); and a Paper on Photography on Wood, by Mr. Contenci. A report of the proceedings will appear in our next.

New Photographic Periodical.—We observe that a new French Photographic journal is announced to appear fortnightly, under the joint-editorship of M. Lacan and Herr Liesegang, our esteemed German correspondent. The title of the new aspirant for the suffrages of the reading photographic public is, *Le Moniteur de la Photographie: Revue internationale et universelle des Progress de la Photographie.*"

Architectural Photographic Society.—A lecture was delivered at the society's rooms, on Tuesday evening, on the Collection of Indian Photographs, by James Fergusson, Esq., F.R.A.S. The lecture consisted of an interesting explanation of the peculiarities and beauties of the Indian Architecture, its immense importance as a historic record, and the value of photographs as affording persons in this country efficient means of studying and systematizing such records. He urged the importance of procuring complete and systematic series of photographs of all the important palatial and ecclesiastical architecture of the Indian empire. An incidental remark on one of the pictures exhibited struck us as important. Referring to the photograph of a fine temple, he remarked, that unfortunately it conveyed no idea of the building, which was really of white marble, and most brilliant in effect; whilst the photograph was somewhat dark and dingy: he presumed it might be due to the non-actinic yellow tinge which the marble might have acquired. On examining the picture at the close of the lecture, we found that, although this circumstance might have had its effect, and under-exposure a little more effect, the chief cause of the dingy appearance which characterized the building was due to a stopped-out sky, which, by presenting a glaring mass of white paper, killed and degraded the tone of the building beneath in a most injurious degree, and thus destroyed its true character.

Popular Science.—We met with an amusing instance the other evening of the various methods of illustrating science for the million. In the street near the National Gallery was placed a table neatly arranged, round the edge of which was placed alternately a stereoscope with slides, and a microscope with objects, for the inspection at one penny per head, of the intelligent *gamins* of London.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St. Martin's-le-Grand.

To Correspondents.

G. H., Boulogne-sur-Mer.—Soluble cotton, made after Mr. Hardwich's formula, can most likely be procured from Messrs. Burfield and Rouch, who now carry these formulæ into effect commercially. The articles on the subject, containing the proportions, &c., you will find in the third volume of the Photographic News. You will find about five or six grains of cotton to half an ounce of ether and half an ounce of alcohol, with two grains of iodide of potassium, two grains of iodide of cadmium, and one grain of bromide of cadmium give a good collodion for most dry processes.

Oxygen.—We fear the method referred to will not be applicable in small quantities. We will give details in a future number.

W. Hooper.—The account in our pages is the fullest yet published. A detailed description will appear in the Transactions of the Royal Scottish Society of Arts; but it is uncertain when, as they are published at rare intervals. A letter to Mr. Hart, at the address given, would be the best means of obtaining fuller information. The descriptions of Ruhmkorff's coil are to be found in various articles scattered through the pages of the *Philosophical Magazine* during the last two years.

Simon Slow Coach.—The mottled effect you describe is frequently the result of a cadmium collodion from which much of the ether has evaporated. It may also result from too rapid immersion of the plate in the bath. 2. The paper referred to is not yet published. It will appear in our pages in due course if found sufficiently important. You will find sufficient information on the subject in the Photographic News Almanac.

An Aspirant.—The writer of the advertisement is doubtless somewhat confused in his phraseology. He probably means colouring positives on glass and on paper with powder colours. Nevertheless, the use of an orange powder colour to give intensity to points of light in weak negatives is sometimes resorted to.

R. G.—The application of a joiner's square to the uprights would enable you to ascertain with perfect accuracy; but the exercise of a little care is generally all that is necessary. In those manufactured by Mr. Meagher there is a gauge given, so as to ascertain at once with certainty. 2. The question of copyright is rather a difficult one. If you give away a photographic copy of a copyright engraving, that might possibly be construed into publication. If you give a copy in exchange, that really is equivalent to selling, as buying and selling are really merely convenient modes of exchange.

A. H.—We have made some enquiries regarding plano-convex condensing lenses, and cannot learn that they are usually kept for sale, as there is not at present much demand for them in this country. They may be procured to order by most photographic dealers. The price of a nine-inch lens of French make is about 30s. we believe. An English made one, of the best glass, would be much more expensive.

J. N.—No. 3. decidedly, as it possesses all the good qualities of all the others, and gives in addition perfect freedom from distortion. The back lens may be used, moreover, as a view lens alone. For a portable camera, Kinnear's, as lightest and most efficient.

O. X. X.—The convex side towards the ground-glass; place the stop at a distance in front equal to about the diameter of the lens. Blacken the edges of the lens before placing it in the mount. There should be several stops of different sizes, from ⅛th of an inch to ½ an inch. ⅜ths is a good size if you have only one. The collodion you mention is not favourable to density, although excellent for detail. Mix with it part of a collodion giving great density.

C. F. B.—See article in the present number, and in Nos. 106, 109, 110, and others. You will find some instructions for colouring magic lantern slides in page 287, vol. i, Photographic News.

W. G. G.—There is no necessity to keep the nitrate of potash solution, and the sulphate of iron solution in two separate solutions, nor is there any earthly advantage in doing so, as they keep just as well mixed; nor will it make any difference with which you mix the acid and alcohol except that the iron solution will not keep well without the acid. Spread the chloride of calcium on a plate, and dry over a water-bath; or if that is not convenient, in an oven.

Tyro.—In Maxwell Lyte's formula for the gold bath the chloride of gold is supposed to be neutral to begin with, before adding the phosphate of soda. The stock solution should always be neutralized at the outset with as small a portion of carbonate of soda as will suffice for the purpose. The use of Maxwell Lyte's or "Theta's" formula is quite a matter of taste; both will give excellent results if fairly used. The disadvantage of carbonate of soda in any excess is its tendency to cause blisters in some papers. Mr. Woodward's pictures are specimens of excellent printing, see his advertisement. We shall be glad to see the specimens and the design you name. Your letter in our next.

N.—The specimen you enclose, which by the way, got provokingly torn in the post, is simply a very good print from an exquisite negative, making a very charming little picture. The circumstances of its printing are somewhat surprising, and would indicate that the negative must be a very vigorous one. We do not remember the article you mention, and cannot at this moment refer to it; but the subject is worthy of consideration. The same effect can doubtless often be produced by different means, but the question to decide is, which is the best and most certain; and that we think is found in the method usually recommended. See the letter of our Parisian Correspondent in this number

Tripon.—We are not skilled in archæology, and cannot give you any idea of the date or value of the stone bottle. The streakiness may arise from the condition of the bath, which would be improved by a minute dose of nitric acid; or it may be from a dirty slide, or from a dirty plate. You may produce magic lantern slides either by camera-printing from the negative, or by superposition. You will find information on the subject in former volumes, and we shall have an article on the subject shortly. The terms for advertising in the Photographic News are to be seen on page iv. of the advertisements.

Justitia.—Will see on reflection, that we cannot publish his letter, notwithstanding the justness of many of his remarks, as it denies, by implication, a privelege to the highest person in the realm which is not denied to the lowest subject, namely the right to select an artist to be employed. Besides, as we have intimated in another column, there is no guarantee that the imperfect and fading prints have been executed by the artist named; it is more than probable they are some of them injurious and disgraceful piracies.

A Constant Subscriber and others in our next.

THE PHOTOGRAPHIC NEWS.

VOL. V. No. 130.—*March* 1, 1861.

PHOTOGRAPHY AND WOOD ENGRAVING.

It is a somewhat singular fact that, whilst any time during the last eight or ten years, discoveries have been constantly made whereby the problem of photographing on wood for the engraver has been solved, or stated to have been solved, each process proposed has remained, to all practical purposes, a complete dead letter. As early as 1854 to our recollection an engraving appeared in the *Art Journal*, photographed on wood and engraved by Mr. Langton of Manchester, who stated that he had then used the process for four years. By what method the photograph was effected, was not stated, but from some very sensible remarks on the conditions necessary, the use of a collodion film is suggested. The conditions are as follows:

1. The block must not be wetted, or it will cast, and the grain will open.
2. No material must be laid on the surface which will sink into the block and stain even the hundredth part of an inch below the surface, or else the engraver cannot see his cuts to any delicacy of detail.
3. Neither albumen, nor pitch, nor any brittle material, can be allowed upon the block, or else of course it will chip in the cross lines, or those close beside each other.
4. Whatever ground of any description is made use of must be so impalpably thin as to be really tantamount to the surface of the block itself, or else it cannot be equally cut through to any degree of certainty.
5. The block should be so prepared for the purpose of the photographer, that his collodion or other preparation may freely flow over it without sinking in, and that it may be easily cleared off in case of any failure in a first attempt, in order that another photograph may be put upon the same block without fresh dressing.
6. The positive must be either a *positive* upon a white ground, (or, the unaltered wood itself) or a *negative* upon a blackened surface.

Various attempts at intervals followed, and in the beginning of the year 1858 a process was patented by Mr. Newton, in which many of the conditions, particularly the saturation of the wood with varnish, appear similar to those detailed by Mr. Contençin in another column. During the same year an article appeared in the *Art Journal*, from the pen of Mr. Robert Hunt, in which similar conditions are again stated, and the thing as *un fait accompli* again announced.

Now, as the advantages of photographing direct on wood, so as to prepare the block for the engraver without the intervention of the draughtsman, must be obvious to every one, it is clear that some cogent reasons, or unstated difficulties have existed to prevent the thing coming into general use. These reasons, we apprehend, may be resolved into three classes; the *vis inertia* of the engravers, or the opposition of draughtsmen; the difficulty of rendering the various tones of the photograph by the conventional lines of the engraver; or, some inherent difficulty or unsuitableness in most of the methods proposed for producing the photograph on the surface of the block.

Regarding the first of these difficulties we apprehend that the enterprise of publishers would soon find means to overcome it, if the other obstacles ceased to exist. The second is more serious: it might be met, however, in the first place, by confining the work to the hands of the few capable engravers who can undertake such work, and in the next, by following out a suggestion by Mr. Hunt in the article referred to, namely, the education of a class of engravers who should be taught to work directly from the photograph, translating its tones into the various effects possible in wood engraving. The third difficulty is manifestly overcome in the process of Mr. Bolton, in which the block appears quite free from any film of any kind, collodion, gelatine, albumen, or varnish. Mr. Bolton having spent much time upon working out his process and being an engraver by profession, is naturally indisposed to give away that, the beneficial use of which the can retain to himself in the exercise of his vocation. As, however, that which is beneficial to the individual in such cases, rarely tends to the advancement of the art, or to the advantage of the public, we propose briefly to call attention to a process to which, so far as we have had opportunity of observing, Mr. Bolton's very nearly approximates.

The process we refer to is that proposed by Mr. Crookes in 1858, and which seemed to have been singularly overlooked, perhaps the liberality with which it was given to the public having really tended to produce that effect. In that process, we believe all the conditions desirable are strictly fulfilled: the cohesion and texture of the wood are not in any degree affected, there is no film to interfere with the operation of the graver, or to become disintegrated in fine cross cuttings; the wood is not blackened below the surface; in short, the block is in all respects in the same state as when prepared by the draughtsman, the only conditions enforced on the engraver being his capability of translating tone into line, and that the block be cut in a subdued or artificial light.

The process, which will be found in detail in our first volume, p. 193, is very simple, and consists in rubbing over the surface of the block a little oxalate of silver moistened with water. The block is then exposed under a negative to direct sunlight, and a print is obtained in the usual manner. No fixing is required, darkening only taking place very slowly, ordinary diffused daylight having but little action on the coating of oxalate of silver.

In all cases of this kind, it is of little purpose to say that such and such processes "probably might answer." It is the fact of having been successfully practised which gives value to the formulæ. The process of Mr. Contençin has, we understand, been practically tested, and considerable interest would have been added to his paper the other evening if he could have shown some specimens of the results. Mr. Bolton's process has been eminently successful, as the engravings in the *Lyra Germanica* attest. But in no instance can a more completely practical and satisfactory illustration be given, than is found in the engraving of the "stereomonoscope" given on page 26 of our first volume, the block for which was photographed by his own process by Mr. Crookes, and engraved by Mr. Pearson, of Bolt Court.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATIONS, AND ANALYSIS.

Next in importance to nitrate of silver stand *iodine* and the various *iodides*. Iodine, as being the body from which the various metallic iodides are prepared, will be described first, although for various reasons we shall not devote so much space to it as we did to nitrate of silver.

Iodine, from the Greek τὸ ἴον, the violet, owing to the exquisitely beautiful colour of its vapour, is found principally in combination with magnesium, sodium, or calcium, in various mineral springs and in sea-water. It is obtained in commerce almost entirely from the latter source, although from the very small quantity present in sea-water (so small that many skilful chemists have altogether failed to discover it), it is necessary for it to undergo a process of concentration by passing through the organisms of certain marine and littoral plants, which have the property of absorbing the iodine from the sea-water when it is found in combination with bases in their ash. From this is prepared as follows:—Varec or kelp, the ashes of various species of marine plants, is placed in water, and then boiled for some time until the soluble salts are all extracted. The liquid is then evaporated to a small bulk, and after filtering off the crystals of salt, &c., the filtrate is evaporated to dryness, mixed with peroxide of manganese, and heated to commencing redness. It is then again dissolved in water, and the iodine precipitated from the solution by means of chlorine. The crude iodine obtained by the preceding process is purified by washing with water, drying, and subliming. The above is a brief outline of the method employed for the extraction of the iodine. We have purposely made it brief, as it is not likely that many of our correspondents will care about preparing this body for themselves. The account could not however have been altogether omitted, as it is necessary to have an idea of the source and mode of preparation, in order to understand its subsequent history. We will suppose that the operator is already in possession of commercial iodine. This will generally be too impure for photographic uses, and it will accordingly be necessary for him to purify it. This may be done in the following manner:—Take a Florence oil flask, and clean it perfectly by boiling a strong solution of soda in it once or twice, finishing off by boiling a strong solution of cyanide of potassium, and well rinsing with water. When quite clean and free from smell of oil, place in it the iodine which is to be purified (one ounce we will suppose) and pour over it about four ounces of strong spirits of wine. Let the two digest together for about half an hour at a gentle heat; at the end of that time the iodine will most likely have dissolved, if not, boil the liquid for five minutes over a gas flame or spirit lamp, and allow it to cool. Whilst it is cooling, place a filter paper and funnel in the neck of a perfectly clean quart bottle, and then pour the alcoholic tincture into the funnel. A clear, dark brown solution of iodine in alcohol will come through into the bottle, and the impurities will be left on the paper; any intentional adulteration with black lead or similar body will in this way be detected. When the whole of the solution has passed through the filter into the bottle, pour into the latter, in a thin stream with constant shaking, pure distilled water, until the bottle is three quarters full; shake it violently for a few minutes, and then set it on one side. In an hour or two, upon examination, it will be seen that the iodine has separated from the liquid and settled at the bottom, in the form of a dark grey, almost black powder, a brownish transparent liquid floating above. This may now be poured off, and the iodine at the bottom of the bottle collected on filtering paper, and allowed to dry at the ordinary temperature of the air in a place free from dust. It must then be kept in a well-stoppered bottle. It may also be purified by sublimation; for this purpose it is to be placed in a glass retort, and heat applied until it rises in vapour, and recondenses in the neck and receiver in the form of crystals. The process of solution and precipitation is, however, easier for amateurs to perform, and although it involves the expense of the alcohol, we think that it is the one which would be preferred on the small scale.

Iodine when purified is of a blackish grey colour with metallic lustre, resembling black lead or micaceous iron ore; it is very soft and friable, and is easily reduced to powder. It crystallizes easily by sublimation, or from solution, forming right prismatic crystals. It transmits light only when in very thin pieces, the transmitted light appearing red. It fuses at 224·5° F., and boils between 347° and 356° F., being converted into a magnificent violet vapour, which is so dark as to be quite opaque when in a stratum of four inches thick. Its specific gravity in the solid state is 4·948. It has a peculiar odour when faint, reminding one of the sea, but when strong being more like chlorine. Its taste is sharp and astringent, and taken internally it acts as a powerful poison. It communicates a transient brown colour to skin and other organic matter. The most delicate test for the presence of iodine is the bright blue colour which it produces when brought in contact with starch paste, the smallest appreciable quantity of iodine being able to be detected by this reagent. Iodine is very slightly soluble in water, one part of the former requiring no less than 7000 parts of the latter for its solution, according to Gay Lussac.

For the preparation of the metallic iodides several methods are employed, according to the metal with which it is desired to obtain the iodine in combination. Several of these compounds are made from iodide of iron, and we propose, therefore, to describe the preparation of this body first, and then to give the modes of making the other iodides from it. In a Florence oil flask, which has been cleaned as above directed, place gradually 2 parts of iodine in a mixture of 1 part of clean iron filings and 10 parts of water. Warm them with frequent shaking, and when the combination is complete, which may be known by the solution becoming colourless or very pale green, filter it into another clean flask. It will now be a solution of proto-iodide of iron, from which may be prepared iodide of potassium, ammonium, &c.

If it be desired to prepare iodide of potassium, add to the above solution, having been previously heated to the boiling point, a solution of caustic potash in small quantities, until there is no longer formation of a dark precipitate, and the solution is very faintly alkaline. Then filter into a china cup, and evaporate to dryness in the manner recommended when we were treating of the preparation of nitrate of silver. When dry, it should be extracted with six times its weight of strong alcohol at a boiling temperature, having been previously well powdered. The filtered solution, after the alcohol is evaporated or distilled off, leaves iodide of potassium, which may be crystallized in the following manner. Dissolve it in its own weight of distilled water, and filter if necessary, then place it in a shallow vessel, on a water bath, covered over with a piece of dry filtering paper, so that it can evaporate without any dust falling in; when about half the water has gone off, remove the source of heat from the bath, and allow it to cool gradually. White cubical crystals will be formed at the bottom of the vessel on cooling, which must be removed by pouring off the mother liquor and draining on a funnel, when dry they will be pure iodide of potassium, and must be preserved in a well stoppered bottle. The mother liquor will yield a further crop on re-evaporation, which will not, however, be quite so pure.

Critical Notices.

STEREOGRAPHS OF ENGLISH SCENERY. By W. Woodward, Nottingham.

We have received from Mr. Woodward a packet of his exquisite stereographs of English Scenery, consisting of views of Fountain's Abbey, Tintern Abbey, Rievaulx Abbey, Bolton Abbey, Easby Abbey, Helmsley Castle, Raglan Castle, Chepstow Castle, and Lichfield Cathedral. There are between two and three dozen subjects, which Mr. Woodward explains comprise all he was able to get during the late unfavourable summer. The wonder is that anything at all was obtained, and still more that anything so excellent as the majority of the photographs before us, which are uniformly specimens of first-class photography.

The first that enforce our attention and interest are the series of Tintern Abbey. This fine ruin has so often been done, both by the painter and the photographer, that one might well have become sated with it, and regard it used up, especially after Bedford's noble pictures; but we examine these stereographs with unabated, or rather with fresh interest. Mr. Woodward has gone about his work with an artist's feeling, and his selection of point of view and general treatment has added, in many instances, a new charm to that which was already beautiful. We especially commend attention to No. 210, "Tintern Abbey from the South East." In this slide, unlike too many photographic views, the object has not been to fill the picture with the building itself, but to compose a picture of which the abbey forms part. For vigour, gradation, arrangement, breadth, and general pictorial effect, this is a decided gem.

The Fountain's Abbey series, consisting of eight views, are in no wise inferior to those of Tintern, and are not the less full of interest because very familiar. The especial charm here again is the selection of point of view. No. 201, "Bridge over the River Skell," is an exquisite slide, in which the transparent water of the babbling brook reflects the dark overhanging foliage, and with the rustic bridge and ivy-clad building combines to form a charming picture. No. 122, "The Bridge leading to the Eleemosynary," is another view to which we commend attention.

The whole of the Raglan Castle series are fine pictures; No. 226, "A View from the Walls," especially pleases us. We have not space, however, to enter into detail as to the merits of each picture worthy of notice. The series throughout are good specimens of photography, and are, with the exception of the white skies in some—not all—possessed of much pictorial excellence.

The negatives are produced by the collodio-albumen process, and illustrate as do Mr. Mudd's and others in the present Exhibition, that there is no necessity for such negatives to be hard and chalky.

One point strikes us especially: the uniformity of the printing, and the rich warm tone which prevails. No higher testimony is needed to the value of the alkaline gold-toning process—which Mr. Woodward, unlike many professional printers, adopts—than these pictures, in which neither meeliness, flatness, slatyness, or any of the manifold sins with which this process has been charged, are here at all apparent. Permanency is here obtained without any sacrifice, but with an accession of beauty.

LETTS' EXTRACT BOOK, prepared for the reception of Various Scraps from Various Sources. London: Letts and Son.

The especial claim which this volume has upon our notice is its suitability as a reception for photographs. It consists of a handsome quarto volume of superfine paper, part of which is manufactured guard-book fashion. To this is added a portion of ruled paper for descriptive manuscript, and another portion lettered for index. The whole is neatly bound in cloth, and supplied with a packet of gummed wafers contained in a pocket in the book. Altogether this will form a valuable photographic scrap-book, and its possession an inducement to the systematic preservation and annotating of photographs.

A LIST OF PHOTOGRAPHIC APPARATUS AND MATERIALS; to which is added Ample Directions for Use, and Instruction for Amateurs. By Thomas Greenish.

This is work combines the novel features of a tradesman's catalogue, and a complete instruction book. The former does not come under our province to notice, but we may remark of the instructions that they appear as simple, clear, and efficient as possibly can be supplied within the limits to which they are necessarily confined.

A MANUAL of PHOTOGRAPHIC CHEMISTRY. By T. Frederick Hardwich. Sixth Edition. London: Churchill.

We have only space to notice briefly that Mr. Hardwich's sixth edition of his valuable Manual is now ready, and that it contains much new and important matter. We shall, in another number, notice the new features in detail.

THE PRACTICAL DETAILS OF THE FOTHERGILL PROCESS.

BY F. HOWARD.*

I feel that some apology is due to you on my part for venturing to engage your time about a subject of which so much has been said and written, namely, the Fothergill dry collodion process. However, having been requested by your committee to lay before the members my process of working, I have ventured to do so, nothing more pressing being before the society. In the first place I desire to intimate to you that what I have to say is pre-eminently practical, and nothing will be brought forward or asserted in this paper that I have not tested and proved myself; and at the same time I would say that my remarks are more addressed to those gentlemen who would desire to produce pictures, than to those who are more inclined to experiment or draw comparisons.

The bath I use is the ordinary negative bath of not less than thirty-five grains to the ounce, and not more than forty, carefully filtered, possessing faint acidity, and tested with a wet plate before commencing to prepare dry ones. The glass I use is the best polished flatted crown, which possesses as fine a face as patent plate, and, after rejecting all curved and thin pieces, is much cheaper and less weighty. The albumen I prepare by obtaining the white of one egg—(which you will obtain best and most free from germ by making two moderate-sized holes, and blowing the egg, after the fashion of boys of bird's-nesting experience), to this I add three parts of water, common or distilled, a little more or less does not matter, beat it well with a silver or wooden fork, or place in a bottle and well agitate till it is all froth. I prefer the bottle, as it is less messy, does not require pouring from one vessel to another, as you can see at once if it has mixed properly; as it will frequently happen, even with distilled water, that the albumen coagulates, and the mixture is full of white opaque flakes, and when rubbed between the fingers is not tackey, and does not possess the gummy feeling which dilute albumen ought to have; this must be thrown away, and a fresh lot mixed. It will generally be found that the clear white of an egg is very nearly one ounce in measure, you will therefore have four ounces of dilute albumen, which will prepare three dozen stereoscopic plates; if you now add some 60 to 100 drops of strong liquor ammonia, and well agitate, you will find the mixture much clearer, and if left for a few hours is very transparent.

The collodion is the most important item of the process; pictures may be obtained with any good collodion, but the plates will have all the characteristics, except sensitiveness, of the collodion, and in an exaggerated degree; for instance, the collodion which gives dense negatives used wet, will give denser if used dry, the long development will tend much to assist density; the collodion possessing half tones will be liable to stains and marks, and will generally lack density. The skies printing through, and a difficulty of avoiding stains, is a very strong feature.

I have, during last summer, tried a great many descriptions of collodion, and those possessing an abundance of half tones have invariably shown stains in drying, quite apparent before development; always occurring in the same place, namely, the upper half of the plate; when drying, I have watched them appearing, they being quite apparent if the plate is held so that the light falls obliquely on it. I can only account for this by imagining that the washings have a disturbing effect upon the sensitive film, and tend to separate and cause a crystallization of the iodides

* Read at the Meeting of the South London Photographic Society, on the evening of Thursday, Feb. 21.

or bromides in the collodion. To prevent these markings I have employed, with some success, the following mixed collodion:—three parts of a collodion giving half tone, to one of a dense collodion, both having been iodized some days, this gives a creamy, powdery film, which is very desirable, and indeed necessary to success.

I will now proceed to describe my method of manipulation. Having the bath ready, and the plates cleaned a few hours before, I take a clean plate and lay it between two pieces of clean blotting-paper, and place upon the top a flat bottle filled with hot water, in the mean time get the collodion bottte, free the neck from dry pieces of collodion, and get the plate-holder, slightly damping the edge of the india-rubber; remove the plate, brush both sides with a broad camel-hair brush, and, being sure that the glass is not too warm, attach it to the plate-holder, coat with collodion, allow it to set, and immerse in the bath. I then take a clean funnel, and push with a porcupine quill a clean piece of sponge into the neck (not too tight) and filter into a clean measure the dilute albumen, whilst filtering I move the plate up and down in the bath, (perhaps it is as well to commence filtering the albumen an hour or so before, as it is a tedious operation). I now take a clean dish, a little larger than the stereoscopic plate, and pour into it about three ounces of filtered rain, distilled, or filtered common water, which has been boiled, and, having removed the plate, drained and wiped the back, place it in the dish—I then hold it on a level with the eye between me and the light, and incline it at an angle sufficient to cause the water to flow completely over the plate to the other end of the dish, then back again, until all greasiness has disappeared, *and one turn more*, remove the plate and stand to drain on a clean pad of blotting paper (meanwhile get another plate and place under the hot water bottle), then attach the sensitized plate, after wiping the back, to another plate-holder, and pour along one edge enough filtered albumen to flow evenly across the plate, then let the surplus fall off the other side, put the lip of the measure to the edge of the plate, and carry the albumen round the edge; flow the albumen still on across and across the plate three or four times, then drain off, and place the plate in another dish of water, enough to cover it; having done so, dip your fingers into a basin of clean water and wipe them, remove the second plate from under the bottle, and coat that with collodion and place it in the bath. Now take the dish of water containing the first plate and agitate so as to cause the water to flow across the plate, some thirty times, throw out that water, and fill again, not allowing the water to fall on the plate from the vessel; again agitate as before, throw away, and a third time fill the dish with water and agitate, then remove the plate, stand on blotting paper, and wipe the back, then remove and place in a cupboard or box, free from dust or light, to dry spontaneously; standing it so that it rests on the corners, thus the right hand top corner on a clean piece of blotting paper, the left hand bottom corner against the wall, or side of the box—your other plate will, after moving up and down in the bath, be ready for the same treatment; by pursuing this method of washing, you obtain a perfectly even sensitive film far more easy than by confining the amount of water to four or six drachms, and much less liable to stains or insensitive patches as will be obtained if you wash under a tap.

Plates thus prepared I have kept for a month, they possess a high degree of sensitiveness; I have obtained good negatives in forty to sixty seconds of well-lighted subjects. Drying by artificial heat I do not approve of, it has never given satisfactory results in my hands, indeed I believe that it is to the power of albumen, gums, gelatine, and sugar to retain an impalpable moisture, that apparent dry plate photography is successful, and if you drive the moisture off by artificial heat you decrease the sensitiveness. This is a matter which I venture to call our Experimental Committee's attention to. The plate may advantageously be varnished round the edges, or albumenized with a camel-hair brush, it prevents the film slipping off in washing after developing.

The development I perform with pyro 2 grains, citric acid ½ grain to the ounce of water, silver solution, fresh filtered, of 10 grains to the ounce. Iron developers I have never tried.

I do not pretend for one moment that this method is superior to any other; I can only say it has answered in my hands perfectly well, and I regret that I have not more specimens to place before you; but if any gentleman desires, during the forthcoming summer, to bring back the reminiscence of a trip into the country, or any object of interest, I should be glad to hear he had given this method a trial, as I have little doubt of his success and consequent satisfaction.

A few words upon development may not be out of place, as more plates are spoilt during development than in any other method. Moisten the film all over evenly and rapidly; the best method is by immersion in distilled or filtered rain-water, have ready sufficient developer in a clean measure to cover the plate, remove the plate from the dish, and rapidly attach it to a plate-holder, keep the moisture well up to the edges, *they are apt to repel the moisture*, and the touch of the finger at the edge or back of the plate driving the moisture rapidly away, the consequence of which is that the developer will not pass over those parts; cover the plate well with developer without silver, on and off two or three times, then add, say, two drops of silver solution *fresh filtered*, to the drachm of pyro solution, well mix; again apply the developer, and if properly exposed the picture will soon appear; at the least sign of turbidness you must throw away the developer and mix fresh, washing out the measure; a peculiar characteristic of a good plate is that the developer does not darken, one allowance developing completely. If the lights are increasing in density too rapidly you may sometimes advantageously wash the plate and commence developing again; but it rarely succeeds. It is very useful sometimes when sufficient density is obtained generally—except the sky, or foreground—to wash, and then confine the further development to those parts requiring it. In conclusion, I shall be most happy if, during our ensuing meetings out-of-doors, I may hear some member say, "I am trying your plan of working Fothergill's process, just tell me how long you would expose for this view?" I shall then think these observations have not been superfluous.

I will, at the risk of reiteration, state what are the characteristics of good materials and successful results. The albumen absolutely bright and clear; the sensitized collodion film creamy to look at, powdery to the touch, and the negative should, when developed, show considerable transparency in the sky, indeed a dense sky is not to be obtained in a properly exposed plate, unless very much over-developed, this, by the way, need give little trouble to anxious workers as white skies are, I believe, out of date and much found fault with by our friends the artist photographers.

Traces of clouds may be frequently observed in dry plates, and if not obliterated by over-development add much charm and softness to the prints.

One word I would add as to the relative sensitiveness of wet plates and plates prepared by this method. I would say that they require from five to six times the length of exposure, never less; but there are many difficulties in the way of arriving at correct conclusions, as I have found that a collodion which is very sensitive when wet is not correspondingly so when used dry.

PHOTOGRAPHY ON WOOD FOR ENGRAVING.

BY JAMES CONTENÇIN.*

A method at the same time facile and practical for producing photographs upon wood for the purpose of wood engraving,

* Read at the meeting of the South London Photographic Society on Thursday evening, February 21, 1861.

has long been considered a desideratum, and has formed the subject of careful research, both in this country and on the Continent

At first sight this problem may not appear very difficult to solve; it would seem, at a mere casual glance, that wood might be treated much in the same manner as paper, or that a collodion film might be used, and the image developed upon it; but we must first consider the difficulties on the side of the photographic manipulator, and then the requirements of the wood engraver, and how they are to be met. Upon carefully considering these two points, and their relation to each other, it will not be difficult to see why so many methods have been cast aside as impracticable.

When a solution of nitrate of silver is applied to the surface of the wood-block, that surface readily darkens upon exposure to daylight. So far well; but we find that it is not only the surface which the solution has affected, but that it has also penetrated deeply into the substance of the wood, and softened it; thus making it far more difficult to cut.

The light substance of the wood, as seen in the cut lines, which is usually an indication of the extent of the engraver's work, is not in this case seen until the block is very deeply cut into.

But the most grave objection, to which I have already alluded, is the change to which the wood is subject. In the ordinary case it is crisp, and presents a certain amount of resistance to the graver. Of course, the block which has received the photograph ought to be equal in this particular to the common ones, but it will be found that the silver salt, and the soda used for fixing, by penetrating so deeply into the wood, have caused it to become in a manner soddened, very difficult to cut, and altogether objectionable.

The use of collodion has been to some extent successful; positives have been developed directly upon the block, the latter having first been coated with black varnish. I have seen a simple subject in process of cutting which had been prepared in this way, and succeeded very well.

Now, should this process answer as far as the preparation of the wood, and its substance being unaffected, which may be granted, yet its use must be limited, the wood engraver must not be expected to perform the work of the draughtsman, or to produce brilliancy, effect, and pictorial excellence from a metallic and sombre looking positive; he asks for a picture upon the block, which shall have all the qualities of the engraving which he is expected to produce, and those who have seen the admirable works of our talented artists in this department will very well understand the engraver's objection.

If photography is to be used, it follows that the photograph on the wood should be equal to a drawing such as that which the engraver would expect from the hands of the artist; it must be upon the surface only, the substance of the wood not being affected, the preparation must not scale or chip during manipulation, and the surface must not be affected by the light to which it must necessarily be exposed in the engraver's hands.

Having noticed briefly these methods, and the objections which are generally found to operate against their use, I shall now proceed to notice a process which I have not only been acquainted with for some time, but have used in practical work for several years.

The first thing which I found it necessary to guard against was the absorbent quality of the wood, and among the substances that appeared likely to correct this, such as gelatine, albumen, wax, aluminous soap, &c., I did not find any superior to the varnish made with gum dammar and benzole,—spirit varnish can be used, as also amber and chloroform varnish; but the benzole varnish is sufficient.

The method which I have used is this:—the surface of the wood is flooded with varnish twice or thrice, until it ceases to absorb the liquid, but no coating is allowed on the surface, the object is simply to saturate the fibre, this being effected, the block is placed aside to dry; I next proceed to coat the face with a white preparation, corresponding to that commonly used for drawing; for this purpose I have used washed chalk or whiting, but I think zinc white answers the purpose better; it is applied with a flat camel-hair brush, the excess being swept off.

When this is dry, the surface is again covered with varnish, and all not immediately absorbed is allowed to drain off, the wood being placed on edge; this last operation lowers the colour of the white coating, but it still remains sufficiently opaque to obscure the grain of the wood.

A solution of gelatine, containing twelve grains to the ounce of water, and twenty grains of chloride of sodium, is poured over the white preparation, and is allowed to drain off at the lower edge.

The block is rendered sensitive by being placed, face down, in a glass tray containing a solution of nitrate of silver, of seventy or eighty grains to the ounce, and kept carefully from contact by slips of glass; in this manner but a small quantity of sensitizing material is needful; a large quantity, by being repeatedly used, might become deteriorated by the white.

It is perhaps needless for me to go into minute details in regard to exposure, &c. I make use of the ordinary pressure frame, without the back, adjusting the block and negative in a way to allow of their being removed and replaced if necessary. I have occasionally placed the negative upon the block without using pressure, adjusting it by three pins, and this has answered very well.

In connection with the sensibility of the surface and the vigour of the image, I must observe that the quantity of gelatine or other organic matter is of the greatest importance. If too small in quantity, the image will not darken beyond a pale slate colour. In explanation, it must be recollected that the solutions being kept entirely upon the surface, and the silver not combining with or acting upon the wood, but only with the gelatine, there must be a sufficient quantity of that material, or of some other organic substance present; on the other hand a large quantity would render the preparation too thick.

This is the method which I have employed for producing photographs on wood blocks.

If performed in the manner I have just described, the coating as regards thickness of substance will be scarcely, if at all, perceptible under the graver; it is much lighter in colour than the wood itself, but not white; the markings of the grain of the wood may be traced through it, and there is no tendency to scale or chip away.

After exposure, the treatment of the image is throughout much the same as upon paper—it is fully toned in the gold bath and fixed in rather weak hyposulphate of soda, the action of the latter must be carefully watched, and a short washing in running water is sufficient.

The negatives taken for this operation should be moderately dense, not of the very intense kind, but with sufficient gradation. when taking them, the collodionized glass should be placed in the slide with the plain side towards the lens, otherwise the impressions from the block would be reversed.

In reference to recent claims for the successful application of photography to wood engraving, I may notice that the process I have used, and which I have just described, (slightly modified sometimes according to the subject) has been in operation since April, 1857.

I have rarely made inquiry about any works for which the blocks I prepared were intended, but I remember one upon the spirit doctrine, edited by William Howitt, and published by the Messrs. Routledge in 1857, containing eight engravings from blocks prepared by me. Also an edition of Longfellow's Poems; by the same firm, with a frontispiece portrait; a few months later I sent a frame containing three blocks, one of them a subject measuring eleven by nine inches, to the London Society's Exhibition of 1858; perhaps some visitors may yet remember them.

It may be that this process, which I have used in the practical department of the art, will be found of service in other hands; and as many are now giving their attention to the subject, I wish to contribute as far as I can to the general stock of information upon it.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 27th February, 1861.

The subject of photographing by the Electric Light continues to claim a large share of our attention in this metropolis; and a special meeting of the society is appointed early in the next month, to be devoted entirely to experiments in that direction. Bingham is engaged with one of Professor Way's Mercurial lamps, and fine results are expected from his superior appliances. We anticipate that our May Exhibition will be rich in specimens produced by the aid of this rival of the sun.

Peroxide of hydrogen, or oxygenized water is soluble in ether. Schönbein, whose name is inseparable from the history of oxygen, has contrived to effect this solution easily in the following manner. He decomposes 15 grains of binoxide of barium with as much diluted hydrochloric acid as is necessary to saturate the baryta. Then add it to about 10 drachms of pure ether, and afterwards separate the supernatant ether from the aqueous solution of chloride of barium. This ether is saturated with peroxide of hydrogen: it gives an intense blue with chromic acid; it deprives permanganate of potassa of its colour in disengaging its oxygen, it turns the tincture of guiacum blue in presence of globules of blood. It is a curious fact that the ethereal solution of oxygenized water may be submitted to distillization without removing its properties. On the contrary, they are destroyed when the ether is treated with common water, and still better by a very dilute solution of potassa.

It is well known that iodine and starch form a compound of a beautiful blue tint; this is iodide of starch: and also, that when this compound is boiled it parts with its blue colour, to resume it again upon cooling. This complex phenomenon, hitherto unexplained, has been examined by Baudrimont, who has arrived at the following conclusions from his experiments:—

1. A solution of iodide of starch remains blue even at ebullition, whenever the iodine is in excess.

When a solution of iodide of starch is heated in a test-tube, we perceive the violet vapours of iodine disengaged from the liquid, while at the same time it becomes discoloured: but if, without stopping the ebullition, a few drops of a solution are added, the original blue colour reappears.

2nd. The decolouration of the iodide of starch by heat is due to the separation of the iodine, the vapours of which remain stagnant on the surface of the liquid.

By a remarkable experiment M. Baudrimont shows two test tubes of equal capacity, each containing a similar quantity of a slightly concentrated solution of iodide of starch, were kept in a state of ebullition for the same length of time, until the blue tint disappeared; then air was blown into one of the tubes, at first into the partial vacuum, and then into the liquid itself. The tubes then left to cool, one resumed its original blue colour in all its intensity, while the other, into which the air had been blown, remained much less coloured.

3rd. The phenomenon of the recolouration of the cooled liquids is due to nothing else than to a redissolving of the volatilized iodine, which re-enters the mass of the liquid from its surface.

Two equal quantities of very dilute iodide of starch were put, one into a broad capsule, the other into a narrow vessel. After both were brought to a state of ebullition, a current of air was blown through the liquid in the capsule: now it was seen. that while the liquid contained in the narrow vase resumed its primitive blue colour upon cooling, that which had been submitted to the current of air remained colourless. M. Baudrimont thinks that the current of air facilitates the expulsion of the vapours of iodine. To determine positively that the decolouration of the iodide of starch is due solely to the evaporation of the iodine, the experimenter enclosed in a tube sealed at both ends, a dilute solution of blue iodide of starch, and although it was heated and cooled thirty or forty times in succession, it always exhibited the two-fold phenomenon of decolouration and recolouration, without losing much of its intensity of colour: which result is very different, as has been shown from what occurs in the free air.

Fluoride of mercury is usually met with under the form of small yellow crystals. Mr. R. Finkiner obtains this substance either by adding an excess of recently prepared protochloride of mercury to a solution of fluoride of silver, or by treating carbonate of mercury by hydrofluoric acid. The formula of these little crystals is $Hg^2 Fl$, their principal properties are:—that they are partially decomposed by the simple action of water into mercurial oxide and hydrofluoric oxide. This decomposition also takes place, probably in a moist atmosphere, for the salt blackens spontaneously in the atmosphere, especially under the influence of light. Heat has less action upon it than water: in dry air it may be heated up to 500° F. without undergoing the least alteration. Treated with potassa, a solution of mercurial fluoride deposits oxide of mercury; with ammonia. it deposits a black precipitate, which subsequently becomes grey. If the liquor be filtered immediately after the precipitation, it is found to contain mercury. After a time it deposits a white salt, soluble in concentrated hydrochloric acid, and containing mercury, ammonia, and fluorine. The mercurial fluoride absorbs in blackening an equivalent of dry ammoniacal gas, To decompose this compound requires only a temperature of 212° F.

It is generally supposed that, in order to obtain a biniodide of potassium, it is only necessary to dissolve iodine in iodide of potassium. According to an experiment made by M. Baudrimont, iodide of potassium is only a simple solvent of iodine. He has observed that when sulphide of carbon is mixed with bi-niodide of potassium, this latter body abandons to the sulphur the excess of iodine it holds in solution, in passing to the state of iodide of potassium (KI). "We may conclude," he observes, "that sulphide of carbon is a more energetic solvent of iodine than IK, as it separates it from the latter."

The usefulness of the thermometer in physical and chemical researches is much impaired by confusion arising from the employment of three different scales by several great nations The old *French* scale (Reaumer's) is generally adopted in *Germany;* while the *German* scale (Fahrenheit) is adopted in *England* and in the *United States;* and the *Swedish* scale (Centigrade) has passed from the hands of Celsius to those of Christine, to succeed the scale of Reaumer *in France!*

The two fixed points in all these scales is the freezing point of water, and its boiling point, under a barometric pressure of 30 inches; now the interval between these two fixed points is variously divided. In the Centigrade scale, it is divided into 100 parts or degrees; in Reaumer's scale it is divided into 80 degrees; while in Fahrenheit's scale it is divided into 180 degrees. In the first two scales the starting point is the temperature of freezing water called the zero (0) this point is at 32° in Fahrenheit's scale.

Now these various scales are a great source of inconvenience and error, especially in converting one into another; besides, the signs − and + required to be used, which still further complicate the data. It is proposed to introduce a new scale, based on the freezing and boiling points of mercury, which would give a range of 400 degrees centigrade, and the signs − and + would be dispensed with. In that case the temperature of melting ice would correspond with 40° centigrade, and that of the vapour of boiling water (Bar. 30 in.) to 140°. Thus the necessity for using the signs −

and + would be obviated. The range between the freezing and boiling points of water would remain 100° as at present.

PHOTOGRAPHY IN GERMANY.

Elberfeld, Feb. 21st, 1861.

PROFESSOR VON BABO, of Freiburg, communicated to me last week that he has made a series of experiments on the action of peroxide of hydrogen (HO_2). In the collodion process he found that this body plays an essential part. It is regularly present at the production of glass pictures, and exercises acaording to the conditions, now a favourable, now an unfavourable influence. The action of this body seems to be one of the causes why in the collodion process the sensitiveness of the film is so much superior to all other processes. I hope to receive soon further communications. You know Schoenbein has made similar experiences with ozone.

The first who spoke of a crystallized combination of iodide and nitrate of silver, is Preuss (*Annalen der Pharmazie*). Dr. Schnauss made the first analysis of it, and found it to be: $AgO, NO_5 + AgF$. Kremer found the same formula. Afterwards Tobler and Stamm, and Risse published their researches, and brought forward the formula $AgT + 2AgO, NO_5$. Risse found also that bromide of silver dissolves in nitrate of silver, and forms with it, after the cooling of the boiling concentrated solution, a crystallizable combination of the formula: $AgBr + AgO, NO_5$. It is decomposed as well as the analogous combination of the iodide by water and alcohol. Even chloride of silver dissolves in a boiling concentrated solution of nitrate of silver. After cooling, a crystal arises, consisting of much nitrate of silver and little chloride of silver, without a defined formula. The chloro-nitrate of silver—as one would call this combination—is remarkably insensitive to light, dissolves in a little water, is decomposed by much water.

Professor von Babo publishes, in the *Photographisches Archiv*, a method of producing microscopic stereographs, or, properly speaking, the stereographic production of microscopic subjects. The microscopic photograph gives only a clear picture of a very thin stratum of the object. He hoped to get better definition on one side by the ordinary stereoscopic effect, and on the other side by focussing in the first picture the superficial parts of the object, and in the other one the deeper parts. The success was as expected. Made in the latter manner, the two pictures give, of course, no stereoscopic effect, they appear only as a more perfected design. But when the inclination of the object to the axis of the microscope is changed for each picture, photographs are obtained which under the stereoscope give the same effect as the ordinary stereographs. The photographs were produced upon collodion, and by direct sunlight concentrated by a lens. Dr. Schnauss publishes his researches as to the effect of lead salts in photography. The chloride of lead is white as the chloride of silver, but it does not blacken in the light. The iodide of lead is of a beautiful yellow colour, which changes to green under the action of light; it dissolves in boiling water. The addition of iodide of lead, dissolved in an alcoholic solution of iodide of potassium to the iodized collodion, gave no remarkable effect, although the quantity was considerable. A glass plate coated with iodized collodion, and dipped into a nitrate of lead bath, immediately yellow iodide of lead is formed in the film, which gradually becomes lighter, and seems to dissolve at some parts. If such a plate is exposed in the camera and coated by gallic or pyrogallic acid, no action of light is remarked; if some nitrate of silver is added to the developer, the iodide of the film is immediately dissolved; namely, the iodide of lead is soluble in great proportion in a solution of nitrate of silver; but no double combination of the two salts is formed. When a solution of iodide of lead in nitrate of silver is diluted by water, iodide of silver is separated, and nitrate of lead remains dissolved. The nitrate of lead is not detrimental to the nitrate of silver bath, often in the contrary favourable. A little of this salt may be introduced into new nitrate baths in order to saturate them quickly with iodide of silver. The lead salt aids the quicker formation of the iodo-nitrate of silver.

In a similar manner acts the nitrate of lead recommended by Gaudin as an addition to the nitrate bath. By double decomposition nitrate of silver is formed, which dissolves in the nitrate solution. This explains how this salt can give to the bath peculiar qualities, viz., a great ability of reduction under the developer. In this case gallic acid may be used as a developer. The gallic acid forms, with nitrate and acetate of lead, a yellowish white, with nitrate of lead a greyish black precipitate; this colouration announces a reduction, and proves the importance of nitrates in the bath. Nitrate of lead dropped into a solution of nitrate of silver produces no precipitate, but when nitrate of silver is dropped into a solution of nitrate of lead, a crystalline white precipitate of AgO, NO_3 is formed. This salt is much more sensitive to light than the nitrate of silver. When iodide of silver or lead is added to it, it blackens immediately.

I can recommend to your readers the new tannin preservative process of Mr. Russell; some experiments I made with it after the formulæ contained in Mr. Hardwich's "Photographic Chemistry," were followed by excellent results. PAUL E. LIESEGANG.

Proceedings of Societies.

BLACKHEATH PHOTOGRAPHIC SOCIETY.

THE monthly meeting of this society was held at the Golff Club House, February 18th, 1861, the President C. HEISCH, Esq., F.C.S., in the chair.

The minutes of the last meeting were read and confirmed.

The CHAIRMAN said he had great pleasure in informing the society that Mr. Negretti had kindly brought down a number of very beautiful views for their inspection, and had also promised them some interesting particulars concerning them. Before asking him to proceed, he wished, however, to make a few remarks on a subject to which he had recently drawn their attention, viz., the toning of positives. He then said:—The remarks I made on this subject, a short time since, have called forth a good deal of opposition, and I make no apology for again referring to it, because it is so all-important that it cannot be too fully discussed. At the present moment, too, toning is under consideration at the London Society, so that the time is particularly favourable for a complete investigation. I have been accused of a wish to drive people back to the abominations of sulphur toning, yellow skies, &c., &c. Such accusations are simply absurd, as anyone taking the trouble to read my remarks, will at once see. I stated the precise method which had, in my hands, yielded permanent prints, and I am not to be made responsible for the result of a very different mode of proceeding. Some remarks of quite another character, however, appeared in the *British Journal of Photography*, from the pen of its much respected editor, and to these I replied in a subsequent number of the same journal. In the current number the editor has done me the favour to reply to this communication, and Mr. Hardwich has also referred to my remarks; but neither of these gentlemen has really touched the question which I raised. At the risk of a little repetition, I will re-state what I consider the weak point in the alkaline process. It is this; that the pores of the paper, when immersed in the hyposulphite, are filled with a mixture of chloride of gold and carbonate of soda, precisely the same substances which are put into the hyposulphite of soda in the modification of the older process which I have for years employed, so that any decomposition which in that process takes place in the bath, takes place in the paper in the alkaline process. If any deposit take place in the old bath, it can be removed; in the new process it must remain in the paper. The editor of the journal above referred to, in his first article dismissed this by saying that the pores of the paper were not full of the substances in question, as it was customary to well wash the prints before placing them in the fixing bath. This assertion led me to read over again all that had been written on the subject, to find if any such elaborate washing as is necessary *to remove the solution from the pores of the paper*, had been any where recommended, and I find nothing of the kind. Mr. Hardwich (one of the great apostles of alkaline toning) simply says, "wash for an instant under a tap," that is, just remove the solution from the surface, not from the pores, of the paper. We all know the amount of washing required to remove solutions from the pores of paper; witness the time and trouble required in the last washing of our prints, and I fear if such a washing be needed between toning and fixing, the process would meet with but little favour, and stand a very bad chance of being generally well carried out. In my reply to the first article, I pointed out these facts, but in the second no notice is taken of the matter; but I am told that I have not pointed out a weak point in the process. I think I have. Mr. Hardwich, while not noticing this point, incidentally makes my objection even stronger than I did, by converting what I spoke of as only probable into a certainty. He says, "In all cases, a liberation of sulphur takes place on mixing the above salts (chloride of gold and hyposulphite of soda) even supposing the free acid to be removed from the chloride of gold by neutralizing with a base." Therefore sulphur must be deposited in the pores of the paper. I also pointed out in my letter to the *British Journal*, what has too much escaped attention, that toning goes on as much in the hyposulphite as in the gold, inasmuch as the colour of the prints is totally different when they leave the so-called fixing bath, to that which they possess when they go in. To what is this colouration due, if not to some reaction between the matter of which the image is composed and the hyposulphite? The respected editor of the *British Journal* adroitly gets out of answering this question by taking hold of my remark, that if it were not so ammonia might be used instead of hyposulphite, and says, you can use ammonia, and your prints will then be the same colour as when they leave the gold bath. Of this I was aware, but it does not affect the question of the prints whose colour has been changed by immersion in hyposulphite. I have never met with any paper which would give agreeable tones if left as they came from the gold bath, and such seems to be the general result of experience. Mr. Hardwich evidently counts much on the change of tone thus effected, and even goes so far as to say better tones are to be got by using old hyposulphite, which looks to me very much like depending a good deal on sulphur for your tone. My belief is, that the final colouring matter of the prints in both processes is the same, and that in the alkaline process, you have at least a chance of a deposit in the pores of the paper, which you have not in the other. I do not think that the quantity of gold deposited on the picture could materially protect it against any injury this deposit may produce, particularly as on the white parts of the picture no such film of gold exists. Whether this deposit is of any consequence, I do not at present pretend to say, but I shall watch it carefully before altogether giving up my old friend. In reading over again what has been written on this subject my attention was attracted by one statement which had before escaped me, viz., that papers prepared with chloride of barium could not be used for the alkaline toning. I have, as most of you know, always advocated barium papers as yielding more stable pictures, and requiring less over-printing than others. I continued to use them with the alkaline toning, and still found them far preferable. I have recommended them to a good many, and none who have once tried them will ever use any other. All Mr. Heath's pictures in the Exhibition are printed on barium paper and alkaline toned. I also produce some printed and toned in the same way. The reason given for believing that these papers could not be used, is so curious that I can only attribute it to utter inadvertence. It is, that when the barium salts come into contact with the carbonate of soda, carbonate of barium will be deposited. Now in the first place, when the paper is on the silver bath, most of the barium remains in that bath as nitrate, and what little is left in the paper in the soluble condition (and that only could be affected by the carbonate of soda) is removed along with the free nitrate of silver in the preliminary washing of the prints. Practically, I believe barium papers are very superior, as correcting all tendency to blueness of tone.

In conclusion, I would remark that all authorities, Mr. Hardwich included, are agreed that prints properly prepared by the double hyposulphite process are "permanent," a word which does not admit of degrees of comparison. I trust that alkaline prints will prove so too, but I cannot admit that experiments with moist sulphuretted hydrogen, are parallel with the wear and tear of years. That which might stand one might yield to the other, and *vice versa*.

It must also not be forgotten that my attention was called particularly to this point by observing signs of fading in some alkaline toned prints. This must of course only be taken for what it is worth, but it is a fact as far as it goes. Mr. Negretti, who is present, must have had great experience in printing, and I shall be very glad to hear if he has made any observations on this subject. I produce some prints of various ages, with one exception none less than four years old, which show no signs either of fading, or yellow skies. There is one also toned with sel d'or after having been fixed in hyposulphite of soda, in the year 1851, a process now pronounced by some to be impossible.

Mr. Negretti said that he could give no decided opinion on the relative stability of prints toned by the two processes; but he might mention as a fact, that many of Mr. Frith's last series of views in Egypt, which wére toned by the alkaline process, had faded, while the earlier series, toned in hyposulphite and chloride of gold, were still perfect. The washing in both cases having been equally carefully conducted. One circumstance, however, he thought would materially interfere with the use of the alkaline process in large printing establishments. This was, its effect on the health of the operators. He had himself introduced it in his business, and his operator's hands were very shortly afterwards covered with pustules, which broke and became bad sores. Thinking this might be due to something in the man's constitution, he had set others to the work, but always with the same result. At the skin hospital, where these men had gone, they pronounced them poisoned by the gold bath. In one man the poisoning had gone so far as seriously to affect his sight. He (Mr. Negretti) had been obliged to return to the old process, and if he ever proposed to have anything toned by the alkaline method, he was told by his employés that he must do it himself. Mr. Hayward, of the firm of Frith and Hayward, had also suffered from the same cause.

Mr. Negretti then exhibited a large number of transparent stereoscopic views in Java, Japan, and many other places. The luxuriant tropical scenery was very finely rendered. and some of the pictures illustrating native customs excited much interest.

Mr. Negretti stated that the pictures were printed on albumen, by a process, the details of which he had given at the London Society six years ago, and were toned with a mixture of chloride of gold and hyposulphite of soda. He believed this process was identical with that used by Ferier, who, indeed, had shown it to him.

Mr. Glaisher asked, if this were so, why the French pictures were undeniably better than any produced here?

Mr. Negretti said he believed there were two or three reasons for this. First, Messrs. Soulier and Ferrier used almost exclusively albumen negatives, instead of collodion, and these would bear pressing more firmly against the plate in printing than even well varnished collodion negatives, and besides, there was no varnish between them and the plate on which they were printed. So liable were collodion negatives to be injured by printing on albumenized plates, that when he had a very fine one, such as one of a Theatrical Performance before the Emperor of Java, a print from which he produced, it was kept from absolute contact with the plate by a thin paper all round the edge. In order to prevent, as much as possible, any light going obliquely through it, it was then placed at the bottom of a box some feet in depth, and exposed thus to light from the sky. Another reason was that Messrs. Soulier and Ferrier were able to attend to the printing themselves, and their great experience enabled them to tone better than could be expected from any one who simply did it because he was paid to do so. He believed that if the English amateurs would take up the albumen process, and give as much time and attention to it as they did to other processes, the French pictures would soon be equalled. He then remarked that it had been supposed by some that the negatives of Soulier were larger than the positives, and were reduced in the camera. This he knew to be a mistake. He had seen numbers of their negatives, amongst others, the Bridge of Prague, and they were all stereoscopic size. In order to get the prints in the right direction when viewed as Soulier's are, through the glass on which they are printed, the negatives are taken through the glass, the focussing screen of his camera having the ground side towards the operator.

The Chairman asked Mr. Negretti how long he found albumen plates could be kept after being rendered sensitive?

Mr. Negretti said, for the purpose of printing not more than three or four days. He preferred rendering them sensitive at night, and printing in the morning.

After some further conversation, it was proposed by Mr. Glaisher, seconded by Mr. Spurrell, and carried unanimously, that the best thanks of the society be given to Mr. Negretti for his kindness in bringing his views, and affording so much information concerning them, and the meeting adjourned.

South London Photographic Society.

The usual monthly meeting was held in St. Peter's Schoolroom, Walworth, on the evening of Thursday, February 21st. The Rev. F. F. Statham, B.A., F.G.S., in the chair.

The minutes were read and confirmed, and some specimens and apparatus were examined. Amongst the former were some exquisite card portraits by Mr. Lacy, of Ryde, and a fine specimen of reproduction from an oil painting, which was contributed to the society's portfolio by Messrs. Sydney Smith, and Valentine Blanchard.

A very large and handsome Kinnear's camera was shown by Mr. Meagher. It was intended for plates 18 in. by 16 in., and was fitted with double backs for dry plates. The outer dimensions were 21½ in. by 9¼ in. and 5 in. deep. The full extension of the bellows gave a focal range of 33 in., whilst a cone, with which it was furnished for placing in front, extended the range, for copying purposes, to 60 inches. It was of polished teak, and was fitted with all the adjustments described in a former number of the Photographic News.

The following gentlemen were elected as members of the society:—Mr. Wm. Price, Mr. Burrows, Mr. James Contençin, and Mr. J. Baldwin.

Mr. Burr, in the absence of Mr. Fry, who had undertaken to open the further discussion on the application of photography to astronomical, meteorological, and magnetic registration, made a few further remarks on the subject. He had, in the first place, to call the attention of the meeting to one of the first daguerreotypes of the moon. It was taken by Mr. Bond before 1851, and shown at the Great Exhibition of that year. It was his impression that all these daguerreotypes had gone back to America, but he was happy to be able to exhibit the present specimen, which was very delicate and full of detail. In regard to the question which had been raised at the previous meeting, as to the varying relation between the visual and actinic foci, he had made one or two experiments. He had not had an opportunity of testing for variation of the actinic focus, but he had done so in regard to the visual. It had already been ascertained that the actinic focus did vary, but no observation appeared to have been made in regard to the visual focus: and he had thought that if, on observation he had found any variation in the visual focus from atmospheric or other causes, it might be assumed that the variation in the visual and actinic focus were coincident and in similar ratio. He had not, however, detected the slightest variation in the visual focus during the last month, during which, however, he had only had a variation of temperature of about eight degrees. Whatever might be the truth, however, on this point, he thought there could be no doubt as to the superiority of the reflecting over the refracting telescope for photographic purposes. There was an explanation of the possible varying relation of the foci, which had been suggested to him by Mr. Huggins. It was the effect of temperature on the glass itself. He had a famous object-glass, made by Clarke of America. It had been used by Mr. Dawes, who knew its powers well. On parting with it, he explained that it had its best point of temperature, which showed that there might be some change in the condition of the glass, most probably in the flint glass. There was another point. At the last meeting he had quoted a statement made by Mr. Warren De la Rue to the effect that he had gained very little in time by his contrivance to receive a direct image, and dispense with the necessity of a second reflection. Some doubt was expressed as to the correctness of this idea; but he thought a statement by such a careful and able observer as Mr. De la Rue should be received as of some authority. Mr. Burr then proceeded to suggest an explanation in the possible similarity between the actinic rays and the non-luminous heating rays which did not readily pass through glass; as illustrated by the method of keeping greenhouses warm during the night. An allusion had been made at the last meeting to the effect that we did not know whether the moon sent heat to the earth as well as light. It had been ascertained by Mr. Piazzi Smythe, in his experiments on Teneriffe, that the moon did send a small amount of heat to the earth. It was probable that a good deal of the heat actually reflected by the moon got absorbed in its passage through the atmosphere in dispersing clouds, as it was generally observed that there were fewer clouds at the time of the full moon than at other times. Mr. Smythe had found, by the use of his thermo-multiplier, that the amount of heat from the moon actually reaching the earth is about one-third of that given out by a small candle placed fifteen feet from the apparatus.

Mr. Hughes said one of the chief advantages of photographic meetings was the examination and comparison of experiences, not the mere taking for granted of statements opposed to general experience; and it was a circumstance perfectly familiar to daguerreotypists that they lost a large amount of light by reflection, and of actinism in a similar ratio. He had received, however, what appeared a satisfactory explanation of the apparent discrepancy, from a conversation between Mr. Simpson and Mr. Dallmeyer, in which the latter suggested that in Mr. De la Rue's case the rays striking the reflecting prism amounted almost to parallel rays, whereas, the rays striking the reflector of the camera, many of them fell at a considerable angle. Regarding the question of a varying relation between the visual and actinic foci, he would simply repeat that all photographic experience was opposed to the idea; and it seemed to him reasonable to endeavour, in the first place, to eliminate every other source of error prior to coming to such a conclusion, which, if proved, would involve a much larger question, and tend to throw doubt upon the value of all photographic lenses. Regarding the question of the loss of light by reflection, he knew Mr. Simpson, who had recently visited the Observatory could say something interesting on the subject, and hoped the Chairman would call upon him for some details.

Mr. G. Wharton Simpson, in response to the chairman's call, said he had the pleasure of a recent visit, by the permission of the Astronomer Royal, to the Observatory at Greenwich, in company with Mr. Fry. It was the intention of that gentleman to have detailed some particulars of that visit in opening the present discussion, and he (Mr. Simpson) had not come prepared to enter into any account of it. In the absence of Mr. Fry he would, however, refer to one or two points. They had confined their visit to the meteorological and magnetic department, and had there the pleasure of witnessing in operation the beautiful processes for magnetic and meteorological registration, which Mr. Burr had so ably described at the last meeting. Mr. Glaisher, the superintendent of that department, had with much courtesy entered into very interesting detail as to the working of the various processes. Regarding the explanation of the existence of reflection without loss of light or actinism, to which Mr. Hughes had referred, he (Mr. Simpson) had been especially struck with a fact to which Mr. Glaisher had called his attention. In one case where it was required to obtain two distinct pencils of light from one flame, to trace two parallel lines at a few inches from each other, one was obtained by the direct action of the light, and the other by means of a double reflection by means of two prisms; the image of the flame was received on one prism placed opposite to it, and was again thrown on to the surface of another prism placed in a tube at the proper distance beneath it, the reflection from the second prism being brought to a focus on the sensitive paper where its action was required. Now, contrary to what might have been anticipated, the actinic power of the light which had undergone two reflections was not perceptibly less than that derived from the direct action of the same jet of napthalized gas,—the images produced directly and by reflection being both equally clear and vigorous. In a subsequent conversation with Mr. Dallmeyer on this subject, that gentleman had suggested that the rays of light proceeding from any body parallel to the reflecting surface and impinging upon it directly at right angles, suffered very little loss; it was only when these rays struck the reflecting surface obliquely, that much loss was suffered, and the loss was just in ratio of that obliquity of incidence. By the rays striking a reflecting surface at an angle of 75 degrees, about 370 out of a 1,000 were lost. This circumstance would account for the difference between the experience of the daguerreotype artist who received his image on a small reflecting surface, and consequently lost many of the rays, and that of Mr. Warren De la Rue and Mr. Glaisher. There were one or two other points to which he would advert as interesting to photographers. He had been struck with the beautiful certainty Mr. Glaisher had obtained in his operations. One sheet of paper was prepared and placed upon the cylinder to receive the magnetic registration of twenty-four hours. The professional portraitist or the landscape photographer had opportunity of trying several pictures of the same subject; if one failed, another might succeed; but here, the failure of this one sheet would be the loss of a day's records. In reference to the extreme sensitiveness of the paper used for these records, Mr. Glaisher stated that his object had not been so much to prepare a paper with the highest possible degree of sensitiveness, as one which would retain, during twenty-four hours, the most uniform rate of sensitiveness. The explanation of this distinction arises out of a curious fact which he stated as constantly occurring in his calotype experience. He had always found that the action of light once set up in the excited calotype paper, continued progressing after the exposure had ceased. Thus, of two sheets of paper exposed in one day and developed in the evening, the one exposed in the morning would require only three minutes to come out as perfectly and vigorously as a sheet exposed six minutes with exactly the same amount of light later in the day. The difference being, that the action of light set up in one had continued for some hours after the sheet was put away, whilst in the other development followed at once, and the whole effect had to be obtained by exposure. Recognising this fact, Mr. Glaisher had to produce a paper which should retain, as nearly as possible, an equal degree of sensitiveness during twenty-four hours, so as to get uniform action during that time. He had certainly succeeded admirably. The paper was prepared, if his memory served him correctly, first by a treatment with a solution of iodide and bromide of potassium, 8 grains of the former to 12 of the latter, which was applied with a glass rod. It is then sensitized, also by the aid of the glass rod, with a 50-grain silver solution. It was placed upon the cylinder damp, and, by means of a piece of wet rag wrapped round one end of the inner cylinder, a slight amount of moisture was maintained during the whole time of exposure. There was no visible image produced by the pencil of light, but the development, with a saturated solution of gallic acid, gave generally a most satisfactory and well-defined image. The process appeared to possess the utmost certainty, and Mr. Glaisher might fairly be said just to have hit the maximum of sensitiveness to artificial light combined with uniformity. Another point of interest to photographers was the artificial light used to obtain these registrations. The usual yellowish orange-colour of the gas would be comparatively useless without the contrivance for combining with the common carburetted hydrogen the vapour of naptha, which gave a beautifully pure white flame. This was effected by diverting it from the usual pipes and making it pass through a naptha box, where it traversed 20 or 30 feet of pipe, and was made to combine with the vapours produced by heating naptha. The qualities communicated to this gas by this process were most important in a photographic point of view, for the flame seemed to acquire a very large amount of actinic character. Mr. Glaisher described the process as simple and inexpensive. Before sitting down there was one more suggestion he would make, which was that the mode of preparing paper adopted by Mr. Glaisher seemed, from its sensitiveness and certainty, peculiarly suited to the purposes of gentlemen who were experimenting in the production of developed prints by means of the solar or other enlarging camera.

After some further conversation,

Mr. Burr at the request of Mr. Hughes, made a few remarks on the connection between magnetic perturbations and the spots on the sun, which recent observations seemed to have established, showing that magnetic undulations were caused by changes taking place in the sun. Looking at the question in this light, he said we might regard every vibration of the magnet as a telegraphic message from the sun. Independent observers at different times and places had found there was a periodicity in the recurrence of those perturbations known as magnetic storms, and that in the presence of spots in the face of the sun, and that the maximum and minimum periods of both occurred together.

After a few words from the Chairman on the interest and importance attaching to the subject.

Mr. Howard read a paper on the "Practical Details of the Fothergill process." (See page 99).

Mr. Thomas Clarke handed round for inspection, some stereographs from negatives prepared by the Fothergill process, which had only been exposed 20 or 30 seconds.

Mr. Hughes remarked that, with all due deference to Mr. Clarke, he must urge the importance of abundance of exposure, and the specimens handed round, he thought would have been better if they had been exposed at least twice as long. He thought one of the chief charms of the best pictures in this year's Exhibition arose from this very circumstance that they had been exposed sufficiently to give transparency and detail in the deepest parts of the deepest shadows. The tendency of good photographers was to expose longer than of yore, and the consequence was a softness, a delicacy, and truth, before unattained. He would refer especially to two illustrations, the pictures of Bedford and Mudd. He had recently been in conversation with an intelligent amateur, who remarked that Mr. Bedford regarded full exposure as a *sine qua non* in the production of first-class results, and mentioned one picture to which he gave twenty-five minutes exposure with wet collodion.

Mr. Clarke thought that in some instances energetic and long development might be substituted for long exposure.

Mr. Hughes thought not. Where extreme rapidity was necessary, wet collodion could be used; but it was an important point to remember that the value of a picture did not depend on the rapidity with which it was produced, but upon its excellence when finished.

After a few words from Mr. Howard confirmatory of this view, and some remarks from the Chairman,

Mr. Wall laid on the table a continuation of the report of the Experimental Committee, and moved that it be taken as read. (See p. 90, in our last.) He announced that a meeting of the Experimental Committee would be held at his studio on the following Wednesday evening.

Mr. James Contençin then read a paper on "Photographing on Wood for the Engraver." (See page 100).

Mr. Valentine Blanchard remarked that it was customary with valuable wood engravings to soak them in turpentine when they came out of the hands of the engraver which rendered them unabsorbent of water. He should imagine that such a preparation would prevent silver and other solutions penetrating even better than the varnish named.

Mr. Hannaford had made some experiments in transferring the collodion film to the wood block, which he had first coated with gelatine. He had used a transparent positive for the purpose. He had not carried out the experiment to any practical extent, but so far as he had himself tried it with the graver, it appeared to cut crisply, and might, he thought, be made to answer the purpose. He also referred to some experiments he had now in hand for producing similar blocks to those of Herr Pretsch, regarding which he had sanguine hopes of success.

Mr. Howard suggested that the great difference between the delicate gradations of tone produced by the photograph, and the mode of rendering tones by lines and hatching in wood engraving, would be a great difficulty in the way of using photography on the wood block.

Mr. Contençin said that undoubtedly those engravers who were merely mechanical would not succeed; but some were artists, and able to cut blocks prepared in tints.

Mr. Wall had executed drawings on wood for the engraver, which were washed in Indian ink.

Mr. Simpson could not but think there were difficulties in the way which they were not fully realizing. He remembered, as as early as 1854, an engraving appeared in the *Art Journal*, stated to have been photographed on wood by Mr. Langton. It was not stated how the photograph was done, but it was stated that he had been able to do it for some years, Yet in the face of the means being in existence for ten years, photography was still comparatively unused by engravers. He thought the real difficulty existed, not so much in methods of obtaining photographic impressions on the surface of the wood, as in the impossibility of translating the multiplicity of delicate gradations of tone in the photograph into the few effects obtainable by line hatching in the engraving, without the intervention of a draughtsman familiar with the work.

Mr. Contençin did not ignore the difficulties, he merely suggested that there were some engravers able to meet them.

Mr. Wall did not see that the difficulty was at all insuperable. If the photograph contained 200 tones, and a wood engraving only 12, it would be the business of the engraver to represent the 200 tones of the photograph by the 12 possible in the engraving.

Mr. Simpson contended that this was just the difficulty. It was supposing the wood engraver to be able to classify the 200 tones of the photograph into the 12 of the engraving, and arrange them so as to produce the right effect, which was really the work of an artist possessing the requisite technical skill. Mr. Bolton, who had recently made a claim on the subject, was, he believed, an accomplished and artistic wood engraver, and a photographer. His pictures he (Mr. Simpson) believed were not fixed, but required to be worked in a subdued light. Possibly a process similar to that proposed by Mr. Crookes was used.

An animated conversation then arose, in which Mr. Wall, Mr. Contençin, Mr. Hannaford, Mr. Simpson, and others took part. After which—

The SECRETARY read the following announcement:—It is requested that all monies due to the Society will be at once paid, or forwarded to the Treasurer, Mr. Frank Howard, of 12, Whittingham Villas, Studley-road, Stockwell. Each member's subscription merely covering the expenses of the presentation print and the year's subscription to the journal, the Treasurer is inconvenienced by such non-payments and the cash absolutely required for current expenses. The Committee have incurred sundry expenses for table accommodation, for small expenses connected with the Experimental Committee, &c., sums trivial in themselves, but of importance to so young a society, with so small an annual subscription.

A paper was announced on the subject of "Intensifying Processes as Adjuncts to Instantaneous Photography," by Mr. Valentine Blanchard.

After the usual votes of thanks the proceedings terminated.

Photographic Notes and Queries.

PERMANENCY OF ALBUMENIZED PRINTS.

SIR,—Some discussion having taken place lately on the subject of the relative permanence of the old and new toning process, will you permit me to ask the gentlemen who have taken part in it, whether the idea has ever suggested itself to them, that *no process* of toning *can ever* be permanent with *albumenized* paper? or in other words, whether there is not a something in the composition of the natural albumen that will always, sooner or later, cause the fading of the positive proof? at least, an experience of six years, has convinced me that plain paper proofs, even by the worst of toning processes, are less liable to change, and never, as far as I have witnessed, become of that awfully jaundiced complexion (that we so often see in albumen prints) whether it be the slight trace of sulphur said to exist in the natural albumen, or from whatever cause it may arise, I fully believe that even the excellent toning process now in use, although it may tend to defer the day of doom, will not altogether avert it, instead, therefore, of devoting every attention to the toning part of the process, permit me to suggest to those who possess both time and talent to devote it to seeking some good substitute for this treacherous compound, which I fear has found more favour than it deserves, on account of its usefulness in the dry processes. I am, sir, yours &c. B. L.

ANOTHER GHOST.

SIR,—In the last number of your journal appeared a letter from Mr. F. Lane, recording a curious photographic phenomenon; which, as it appears to be of rare occurrence, may be worthy of corroboration.

Some time ago, having a number of dirty glass plates, and wishing to utilise them, I cleaned them with every possible care to ensure chemical purity, and took some of them out with me to photograph a view in the neighbourhood of Dublin. As it happened, I somewhat under-exposed the plate, and on development was much astonished to see a ghostly image of a lady, who had sat to me for her portrait at least a month before, looming through the lendscape. The features, dress, and accessories were quite distinct, although too weak to print from—but I kept the double negative as a curiosity for a long time, until, in one of those unfortunate moments too common to photographers, it was broken. From the great care I took in cleaning the plate I am inclined to think that, under peculiar circumstances, the photographic image, and of course the chemicals used in its production, pass beyond the mere collodion film, and act on the surface of the glass itself. It may be that the particular glass in question was of a partially absorbent nature, and became impregnated with the sensitive iodide of silver. It would be a curious result to Mr. Lane's and my experiences if an absorbent glass should be discovered, which would supersede collodion as a *couche* for the sensitive chemicals.
—I am sir, yours obediently. J. J. COGHILL.

PHOTOGRAPHIC PIRACIES AND COPYRIGHT.

DEAR SIR,—In your last number of the NEWS (129) under the head of "Royal Portraits," you remark, "We noticed the other day * * * a whole series of card portraits, which from want of sharpness and the peculiar grain of the paper, which pervaded the prints, bore unmistakable traces of being copies," of course implying pirated; might not these have been *copied* by the firm that issued the originals, I suppose owing to their being "worn out," as I have seen several sets bearing exactly these signs, which were no piracies, but actually bearing on the back the names of a first-class London photographer, and also that of a publisher of Haymarket notoriety, which would disgrace even a minor *local* establishment, much more one we generally hear spoken so highly of.

Do not think, Mr. Editor, that I am trying to throw a blind over these thoroughly dishonest practices, for no one would sooner "show up," any one really pirating; but as a lover of fair play, I hope you will insert this.

In No. 128, in answer to "Lex" you say, "He may photograph copyright engravings for his own private amusement," I would tell "Lex," for his own sake, that the new law, (and no doubt seems to be entertained of its being passed) will pronounce it *felony* to have any copyrights *in his possession*, however obtained: this I think should be more generally made known.
—I am, Mr. Editor, yours, &c., OXONIENSIS.

TURPENTINE WAXED-PAPER PROCESS.

SIR,—In Vol. ii, No. 50 of the NEWS appears an account of the Turpentine Waxed-Paper Process, which I am desirous of trying, but without the second iodizer, which latter, when used, I think the process should be called the turpentine-albumen process.

However, before commencing operations, I should feel obliged by answers to the following queries, or such of them as you are able to answer:—

1. For what purpose is the castor-oil added?
2. How long will the waxed papers keep? "Some time" is very indefinite.
3. Approximate exposure, lens 12 in. focus, $\frac{5}{8}$ in. stop, subject, ordinary landscape, illuminated by the sun; time 2 o'clock in the month of April?

"As long as ordinary wax paper," and "one-third more sensitive," being contradictory, and not knowing the length of exposure required with ordinary wax paper conveys no definite information to me.

4. Will the nitrate bath become discloured when the second iodizer is not used?
5. How many hours would papers keep after exposure before developing?
6. One or more English and French make of papers, suitable for the process?
7. Price of work alluded to in the NEWS?

I trust I have not exhausted your patience by these queries. If I have, my only apology must be the near approach of Spring, and the short time at my disposal for photographic operations.
—I am, sir, yours obediently, AER.

[Will some of our correspondents, who have practised the process, kindly give our correspondent a few hints. The price of the work referred to will be ascertained by writing to Marion and Co., Regent-street, the publishers.—ED.]

CONDENSERS FOR MAGIC LANTERNS.

SIR,—Would some of your numerous correspondents, learned in optics, inform me and other of your readers interested in the subject of magic lanterns, what is the best form of condensing lenses to be used? I see, in your impression of the 7th inst., J. W. Reffitt employs a concavo-convex and a double convex placed almost close together; whilst J. R., another correspondent, uses two plano-convex with convex sides facing each other—how far apart he fixes them we are not told. I have a London made lantern by me, which has a concavo-convex and a double convex, the former made of green, and the latter of uncoloured glass; these are separated about an inch. If your correspondents would further tell us what they pay for their lenses, they would confer a favour on myself and several other of your subscribers, who have already caught this magic mania.
—I am, sir, yours, &c. C. F. B.

[The concavo-convex and double convex are theoretically best, but both will answer the purpose. Our correspondent will see that the mention of prices and manufacturers can scarcely be suitable for this part of our columns. On these points our correspondents must communicate privately with each other.
—ED.]

Talk in the Studio.

Fracnis Danby, one of England's most distinguished landscape painters of the romantic school, and an associate of the Royal Academy, died last week.

The Spectrum Discoveries. A lecture will be delivered this evening at the Royal Institution, on Bunsen and Kirchhoff's Spectrum Observations, by Professor Roscoe. We hope to give an abstract of the most inseresting features in our next.

Tho "Motoscope." Stereoscopic pictures combined with the "motoscope" are now exhibited in New York, representing persons in motion. The pictures are mounted in the ordinary way, and viewed in a stereoscope which differs from the common instrument only in having a metal screen worked by a spring which alternately passes before the lenses.

Card Portraits.—Tho rage for these portraits is so great in New York, that in many establishments it is necessary to make appointments for sittings a week in advance. A dozen negatives are generally taken.

New Electric Light.—M. Wesolowski of New York has patented an apparatus for obtaining light by frictional electricity. His claim lies for the application and use of bisulphurate of carbon, or any other equally inflammable liquid capable of being decomposed and ignited by an electric spark, and contained in an insulated vessel, in combination with a frictional electric machine.

North London Photographic Association. The usual monthly meeting of this society was held on Wednesday evening. A paper was read by Mr. Barber on a new method of preparing pure nitrate of silver, from metallic silver alloyed with copper, and some remarks by the same gentleman on the sources by which silver is contaminated by organic matter. A brief paper was also read by Mr. C. Jabez Hughes, on Objections to the Hydrometer Bath Tester. The resulting discussion produced many unexpected and interesting facts confirming the value of this instrument. Details in our next.

New Photographic Society.—At a meeting of some photographic amateurs, held on Wednesday week, a new society was formed, under the name of the "Edinburgh Photographic Society." The chair was occupied by Mr. Georgo H. Slight, engineer, who in a few remarks explained the objects of the society. All present were aware, he said, that there was already a photographic society in this city, the annual exhibition of which, now open, was well calculated to improve the taste for the art both among its members and the public; but whilo that society had its peculiar advantages and departments for its members, it had been thought that there was room for another society, if it could be made more easily accessible to the amateur of moderate means, in which more freedom of discussion could be cultivated, and having more frequent meetings of an experimental character would prove more useful to the young photographer. A new society, conducted on such principles, could scarcely be called a rival to the present one, but would rather be looked upon as a useful assistant, taking upon itself no end of drudgery, by discussing subjects which might be considered as beneath the notice of the other, aiming at plain practical excellence, although, in doing so, not necessarily abjuring the refinements of tho art which they would sharo in common with their more matured parent and friend. The projectors of this society had for several months been in the habit of meeting together and and discussing photographic matters in that way, and the pleasuro and instruction they had derived induced them to wish to extend a little further, the present meeting being the consequence. A list of laws for the new society was then submitted to the meeting, which, after slight alterations, were unanimously approved of. On tho motion of Mr. Mure, tho following gentlemen were elected a council of management:—President, J. D. Marwick; Vico-President, G. H. Slight; Secretary, J. T. Taylor; together with Messrs. Robert S. Galloway, Archibald Burns, W. H. Davies, and James Ramage. It was agreed on that meetings be held fortnightly throughout the year, that summer excursions be planned, and that, if possible, a glass house be procured, in which the members might practise portraiture. After several suggestions by Messrs. Valentino (Dundee), Campbell, Flowers, and others, the meeting separated.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32 Paternoster-Row, London.

To Correspondents.

Seaside.—Photographic News Almanack for 1859 is ont of print.

F. P.—Add ether and alcohol in equal parts, rather use an excess of ether to dilute your gelatinized collodion to the proper consistency. "Brande's Manual of Chemistry" is one of the best books published on the subject.

G. H.—The Mackintosh cloth you send might possibly do alone; but with a lining of yellow or black calico it will do admirably.

Orwell.—Our own engagements have not left us time for trying the new American toning process; nor have we received any communication from those who have. Mr. Mac Tear of Glasgow exhibited a print toned by the process at one of their meetings; aud we at once wrote to him asking for particulars, but never received any answer.

W. A. Y.—1. It does not require starching or albumenizing. 2. The silver solution is best applied with a glass rod, and does not require the addition of iodide or bromide. 3. Slightly acid, with acetic acid. 4 Collodionized paper is best excited by floating. 5. We have never tried it; but there is no reason why you should not.

H. T. T.—Is thanked for his courteous letter. He has, however, slightly misapprehended the statement of the case regarding the first item in his letter. In the standard solution given, one ounce is intended to precipitate one grain of silver. One drachm precipitates therefore, one-eighth of a grain of silver. If, therefore, one drachm of silver solution be operated on and drachms of the standard solution instead of ounces be counted, the rate per ounce will be obtained. In fact no matter what measure of silver solution be used, if a similar measure for the standard solution be used, the rate per ounce will be indicated, and herein lies the extreme simplicity and advantage of the formula. The statement in Vol. 1 to which you refer must be an error, for which, however, we are not responsible. The number of prints a given quantity of gold will tone, depends somewhat on the paper and other circumstances, but about 500 square inches for each grain of gold is an outside approximation. The additional syllable in your quotation certainly did not improve the sense, although, fortuuately, it has scarcely made it nonsense.

Albert.—The alkaline gold toning bath had better, in all cases, after toning as many prints as it can be made to do, be thrown away and another made. Each grain of gold will, as we have remarked above, tone from eight to ten whole plate pictures, and it is best to mix just sufficient to tone the number of pictures wanted. Instead of throwing it away, it may be thrown into a separate bottle kept for the purpose, and the remains of gold precipitated with protosulphate of iron. Saturated solutiou of hypo is made by adding as much of the crystallized hypo as the water will dissolve or about 20 ounces to a pint of water. Half the proportion is better for fixing; and use it fresh.

W. H. Warner.—The red spots on the print appear to be the result of particles of something having accidentally fallen upon it; but it is difficult to say what: possibly bichromate of potash. We will propose you as a member at the next meeting of the society

J. S. R. W.—Pinholes in a negative may proceed from a number of causes, one of the most obvious is dust in the camera or the bath. It will sometimes occur from a bath being super-saturated with iodide of silver; and sometimes from the condition of the collodiou, minute portions of the iodizing remaining undissolved in it. Dust your camera well and filter your bath. If this does not effect a remedy, add a quantity of new solution to your bath. If that fails try a fresh collodion, or add a drop or two of water to that you are using: see also that it is quite free from turbidity when you use it. 2. You may add the dry oxide of silver to your bath, taking care to agitate well during a few hours. The same effect will be produced, but more time is required than when the moist oxide is used. 3. Not unless you add too much soda. Take care to reuder it neutral and nothing more. Vol. 4 of the Photographic News is now ready; but the number is limited. To have had as good a supply as might be desirable, we should have had to reprint many more of the early numbers of the volume than would have been commercially remunerative.

Oxygen.—See "Notes and Queries" in present number. We cannot describe the process of galvanizing iron in these columns. Zinc is the metal deposited.

Thos. Wardill.—The vapour of gas-tar had better be kept out of the operating-room.

A Constant Subscriber.—We believe that it would be difficult to prevent the copying of French photographs and selling them in this country; but it is obviously dishonest to do so. The law of copyright as relating to photographs, either English or foreign, is very uncertain and unsatisfactory, and in such case it is well to fall back on a law older than the common law or statute law of this country: "Do unto others as ye would that they should do to you." A silver bath after shaking up with China clay should always be filtered well, sometimes it is desirable to do it twice. The varnish drying in streaks indicates that it is not good: try some fresh. French papers are sized with starch, which facilitates toning more than the gelatine with which the English paper is sized. You can procure the plain paper of any dealer, and albumenize it yourself, if you desire. The black sediment in your toning bath is probably precipitated gold. Liver of sulphur, or sulphide of potassium, can be had of most chemists and druggists, whether they keep photographic chemicals or not; certainly, of all photographic chemists. Opinions are divided as to the best dry process. See Mr. Davis's paper in our last.

G. O. is thanked for his letter and the kind interest he expresses in the News. We value such suggestions, which shall be borne in mind. He must remember, however, there are very many tastes to please. The article in question has been waiting verification by actual experiment, when opportunity and weather could be made to coincide. It will appear shortly. We conceive the articles on Art important and necessary. The "feeling" which our Correspondent refers to as sufficing, is often dormant, and requires to be awakened; or latent, and requires to be developed, and even when awake and active, it requires directing and cultivating. Artistic feeling does not always involve artistic knowledge, whilst the latter often does generate the former.

X. Y. Z.—A pure sample of ordinary resin is recommended. Canada balsam may be used, as may also Venice turpentine. It is not absolutely necessary to use a cadmium collodion; the formula given in the former part of the Almanac may be used. Try the albumen process for interiors; it will give good results.

Several Correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 131.—*March* 8, 1861.

ORGANIC MATTER IN DISTILLED WATER.

We invite the attention of our readers to some interesting experiments made by Mr. Barber—the details of which will be found in another page—relating to the presence of organic matter in new silver baths, and the source from which it is at times derived. Referring to the organic contamination of nitrate of silver, Mr. Warren De la Rue, at a recent meeting of the Photographic Society, referred to the packing of nitrate in paper, as a fertile source of such organic contamination, and a similar remark has been repeated on other occasions. In order to test how far this supposed contamination actually took place Mr. Barber took three bottles containing solutions of pure nitrate of silver in an alkaline, neutral, and acid state, respectively. In each of these he placed a piece of the common wrapping paper used by chemists, and then placed the bottles in sunlight. As our readers are aware, any organic contamination of the silver solution would have been shown by the discoloration of the solution, and the final reduction and precipitation of a portion of silver in combination with the organic matter. No such reduction or discoloration took place, however. The papers blackened, that in the alkaline solution first, then that in the neutral, and finally that in the acid solution, but the solutions themselves remained clear and unaltered. Several samples of distilled water, suspected of being a common source from whence organic matter found its way into the silver solutions, were then tested by the addition of nitrate of silver in the alkaline, neutral, and acid state. These, when placed in sunlight, showed unmistakeable traces of the presence of organic matter. The alkaline solution rapidly discoloured, then showed a deposit on the sides and bottom of the bottle; the neutral solution discoloured more slowly; whilst the acid solution was but slightly affected by the action of light.

These results would be, doubtless, by most persons, quite unexpected, and would lead to a conviction that they had not been supplied with water or kept with reasonable care. Mr. Barber is of opinion that the presence of minute traces of organic matter in distilled water might be quite compatible with ordinary care in its preparation and keeping; and might be accounted for by the accidental contact of a small piece of luting from the still, contact with corks, or with dust from time to time, &c., &c., the possible germ from which vegetation might arise and organic contamination ensue, being derived from some of these sources.

Whatever the source, that it is frequently present in distilled water is manifest, and where it is desirable to prepare a bath of exceeding delicacy and free from the slightest trace of organic contamination, the same methods which detects its presence may be employed with advantage to eliminate it from the water prior to making the bath. Two or three grains of nitrate of silver may be triturated with one grain of oxide of silver to render it alkaline, and then added to water required for the bath. This, on being in strong sunlight, will reduce and precipitate any organic matter in the water, which may then be filtered, and is ready for use. Or, the solution of the strength required may be made alkaline in the oxide of silver, placed by sunlight, and subsequently filtered to remove the precipitate.

We may add, before concluding these brief remarks, that our attention was recently called to the same subject by an intelligent correspondent, who had detected the presence of organic matter in distilled water by the use of per-manganate of potass, a very delicate test for the purity of water. He was struck with the fact that no turbidity, discoloration, or precipitation was produced on making a sixty-grain silver bath with the same water. It is important to remark, that if the silver solution be acid, the presence of organic matter will be less readily shown, and that a very weak silver solution is a more delicate test than a strong one.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Architecture.—The application of photography to this branch of art, fostered and encouraged by "The Architectural Photographic Association," has taken high rank in public estimation, and is rapidly becoming more general. In the lectures delivered at the Exhibition in Conduit Street, the importance of the camera, as so applied, is fully demonstrated, and receives high testimony; and no one can inspect the productions there displayed without being struck with the wondrous perfection they possess. Architecture, like photography, is said to be an art and a science; and it is shown that, although it has been studied by both artists and men of science, its greatest successes have been due to those eminent masters who combined the qualities of both art and science. The architect, who follows in the beaten course of mechanical labour, has but the humble province of a builder of dwellings; but in the hands of the more gifted or more aspiring, this art cultivates the very noblest of our faculties, and is full of a great philosophy, producing works which will be preserved by reverence and love when the nation of the poor forgotten architect shall have dwindled into a name only remembered in connection with his own enduring works. In photographing architectural subjects, the spot chosen for the camera must be judiciously selected. One of the great features in a fine building will be the just and proper balance of parts; and although it is quite true that some portions may have in themselves the most perfect symmetry and completeness, still they are not likely to be discovered by *mere chance;* and the operator should, therefore, make himself sufficiently acquainted with the laws of art to recognise and secure such views as do justice to the origiual design, and fairly represent the real merits of his subject. It is by no means an uncommon thing to observe photographs, otherwise excellent specimens, in which the field of view is limited to some portion of a grand old pile peculiarly uninteresting in itself, although of supreme importance in its relationship with the general effect of the whole. One building is intended to concentrate the entire greatness of the design in its general proportions: another, thick with ornament and details, can only be appreciated from a point of view which embraces but a small portion of the structure; and these considerations should, of course, have weight with the photographer of taste. It must be remembered that the general principles of art have their application in architecture as in all other branches, although of course each will give prominence to those most applicable to its own peculiar purposes.

Art.—Philosophically considered, art includes each and every process by which we acquire that which conduces to our comfort, pleasure, or improvement. In ordinary conversation, this term is very loosely applied; in consequence of which, it is a task of no little difficulty to define its exact meaning. Some arts which have attained to unusual perfection, or display in their professors a greater amount of intellectual refinement and manipulatory skill, have therefore been separated from the arts generally, under such terms as the polite arts, the fine arts, &c. Under these heads we find *Painting*, comprising, strictly speaking, all methods of producing representations on flat surfaces by pencils or pigments. *Sculpture*, or an art producing representations in partial or absolute relief. *Architecture*, meaning, not the method of building, but that which invests them with real beauty, sublimity, or grandeur as works of art: *Music*, the scientific principles of which, though more clearly explained and understood, are really those which are common to all the fine arts. It is now a question whether Photography can rightfully take rank with the arts I have enumerated or not: but sooner or later its claims *must* be admitted; and whether this be soon or far in the future will depend upon the character of photographic productions, rather than upon pretentions based upon a knowledge of the capabilities and powers of the art itself. To our practical operators, therefore, must all lovers of photography look for the advancement and improvement of the art.

Artistically.—Expressing the culture and refinement of an artist's mind as indicated in his works.

Attitude.—The pose of a model. It should give varied outlines, a proper balance of parts, be in keeping with the general expression, and be graceful, easy, unaffected, and characteristic. A graceful attitude will give a degree of beauty to the homeliest man or woman, and render the beautiful more strikingly so. Curved and undulating lines are generally aimed at in choosing the attitude, because of the harmonious and uniform appearance which then unites every part with the whole. Contrast, however, gives vigour, even although it sometimes imply the introduction of an acute angle. It is for this reason we so frequently find the head and body turned in different directions.

I have already pointed out that the attitude should be characteristic, or becoming; for instance it would not be becoming, or characteristic, or, in other words, in *keeping*, to give a plump short girl, with a lively and animated expression, the lofty carriage and queenly attitude of a Juno: nor to force upon slow moving stiff-jointed old age an imitation of that sprightly vivacity of motion which is characteristic of youth. Vigour may distinguish one pose, languor and softness another, majesty that, simplicity this, and yet all may be equally graceful and pleasing. In each case the *expression* (see *Expression*) of the figure must be consistent with that of the face and with the general characteristics of the model. (See *Animated*). *Action* understood as motion only in a limited sense, is the great source of gracefulness of attitude. All the antique models we so study and admire for gracefulness, are represented in action or motion. The fine outlines formed by a swan's neck, or seen in the bounding gambols of a beautiful greyhound, will illustrate the gracefulness which is nearly always implied in the flowing and contrasting lines of a well posed model. Look for grace in the movements of every graceful object, and you will grow in its knowledge, for—

"Graceful—yet each with different grace they *move*."

and the appearance of motion, and the grace of attitude will be nearly always found associated. In my remarks on action I pointed out a distinction between its meaning and that of absolute motion, such as is implied in a falling body, which, when painted or photographed, appears to be suspended in the air, and although it might not seem quite clear, I hope the above remarks will explain what I then meant, and what is usually meant by the use of the technicalities *action* and *motion* in reference to *attitude*.

Remember that *variety* is to be sought, but that it must not destroy *unity*, and that curvature of outline is the primary source of the latter quality; that parallel lines are ugly, although equality of parts is necessary to secure their harmonious balance; that angularity and uniformity should be avoided, although even these qualities are, *in rare cases*, to be sought as adjuncts to the expression of character. In posing, avoid getting the limbs in exactly the same position, the shoulders of exactly the same height, and the head too stiffly erect. The pose of a lady should not have that boldness of action which you would give a man, but be modest and retiring, the arms describing gentle curves, and the feet never far apart. The appearance of motion is secured by removing the centre of gravity somewhat out of the line of the supporting base. In studying these rules, of course, the subject of costume must be considered. The absurdities of fashion, and its eccentric vagaries of form and taste, will sometimes sorely try one's patience; here the photographer has but one remedy, viz. *to conceal.* For this purpose, loose drapery, such as as plaids, cloaks, scarfs, opera mantles, &c., will be best. There is a mistake frequently perpetrated of getting the front view of the body contrasting a nearly side view of the head, but with the eyes looking straight to the front. In such a case all the beauty of motion is gone, and expression is destroyed, at any rate so far as it is pleasing. When the head is in this position, the eyes should indicate that it was turned to look towards an object situated in that direction, and not merely to affect variety of outline. *Art is art only when it is not too strikingly apparent, otherwise it degenerates into affectation.*

Scientific Gossip.

On Friday evening, the 1st inst., Professor Roscoe delivered a lecture at the Royal Institution on Professors Bunsen and Kirchhoff's recent spectrum discoveries.

After a few introductory remarks, the lecturer drew attention to the different colours which certain metallic compounds imparted to flames when they were introduced into them, and illustrated this by exhibiting various flames so coloured. A compound containing the metal sodium gave an intense yellow flame; if a potassium compound were introduced, the flame became violet; lithium caused it to become an intense crimson; calcium a yellowish red; strontium a bluish red; and barium a rich green. It was then shown that when these flames were allowed to illuminate a narrow aperture, and the ray of light so produced analysed by a prism, spectra were seen which exhibit differently coloured bands of light. A diagram of the solar spectrum was shown in the first place, and the dark lines which were seen to cut it across in every part were pointed out. By passing in the same way the yellow flame caused by the incandescent vapour of sodium through the apparatus, the soda spectrum was obtained, in which, instead of all the colours of the rainbow, as in the solar spectrum, there was seen only one bright yellow line, occupying the same position as the dark line D in the solar spectrum. In the same way it was found that when the flames produced by the other metals which gave colours were examined in a suitable apparatus, each metal was found to yield a peculiar spectrum.

The spectrum apparatus in which these results could be seen was exhibited to the meeting; it consisted of a prism incased in a dark box, and on each side of the prism was a telescope, having the object glass pointed to the prism. Through one of these the spectrum was examined, and in the position occupied by the eye-piece of the other telescope (which was removed) was placed a vertical slit, in front of which the flame was placed: by looking through the telescope the spectrum of any flame placed in front of the slit could be seen and examined.

The advantage of this kind of examination was shown to be very great when the chemist had mixtures to deal with; for instance, the lecturer showed a flame which was illuminated with a mixture of 20 parts of potassium salt, and one of sodium. The yellow colour of the latter so overpowered the violet colour of the potassium, that the presence of any of the latter in the flame could scarcely be recognised. If, however, the flame were placed in front of the slt spectrum apparatus, the true spectra were separated, and were each distinctly visible at different parts of the field, where the sodium could be recognised by its bright yellow line, and the potassium by the red and violet lines which it shows. A representation of this appearance was thrown upon the screen by means of a magic lantern, illuminated by the oxyhydrogen lime light.

This holds good with mixtures of all these metallic salts. The spectra of each being perfectly independent of and uninfluenced by each other, could be recognised when the metal was in most extremely minute quantities. The value of this method of analysis was shown in the case of a mixture of five or six alkali metals and earths. In the ordinary processes of chemistry, to detect the presence of these bodies would require two or three hours hard work in the laboratory, and even then minute traces of any substance were liable to be overlooked. In contrast to this, the following extract was read from Bunsen's most interesting paper:—"I took a mixture of chloride of sodium, chloride of potassium, chloride of lithium, chloride of calcium, chloride of strontium, and chloride of barium, containing at most one ten-thousandth part of a grain of each of these substances. This mixture I put into the flame, and observed the results; first the yellow sodium line appeared on a background of pale continuous spectrum; as this began to be less distinct the pale potassium lines were seen, and the red lithium lines came out, whilst the calcium lines next appeared in all their brightness. The sodium, lithium, potassium, and calcium salts were now almost volatilized, and after a few moments the strontium and barium lines came out as from a dissolving view, gradually obtaining their characteristic brightness and form." In this manner were obtained with absolute certainty, in half a minute, what the ordinary processes of the laboratory would scarcely give in three hours hard work. This consecutive appearance of the different lines of the spectra was illustrated by painted slides in lanterns.

The extreme delicacy of this method of analysis was next pointed out; quantities of substances, the smallness of which the mind entirely failed to realize, could be detected with certainty: for instance, of soda the 3,000,000th part of a milligramme, or the 180,000,000th (the one hundred and eighty millionth) part of a grain could be recognised. The method which Bunsen adopted to estimate this minute quantity was said to be somewhat as follows:—Suppose a piece of sodium, weighing one-tenth of a grain, were burned in a large room on a piece of wet blotting-paper, its vapour would diffuse itself through the whole of the room in a very short space of time. It would thus be easy to calculate how much sodium was present in every cubic foot of air. By then calculating how much of this air would pass through the gas burners to illuminate the flame, whilst an observation of its spectrum was being taken, for two seconds for instance, the actual weight of sodium passing through the flame for that purpose could be calculated; and in an experiment of this sort tried by Bunsen, he found that no more than the above quantity need pass through his apparatus in order to be detected. By a test of this excessive delicacy it was found that sodium was always present in the air, and all bodies exposed to the air for a short time gave this yellow line. A piece of clean platinum wire, which was shown to give no yellow colour to flame, was merely touched with the finger when it at once imparted the well-known soda re-action.

Of lithium he could detect, in this way, the 6,000,000th part of a grain, and in this manner it was found that whereas lithium was hitherto only known to occur in four minerals, it was now seen to be one of the most widely distributed elements in nature; it existed in all rocks, in sea and river water, in the ashes of most plants, in milk, in human blood, and muscular tissue. The end of a cigar placed in a flame, and examined by the spectrum apparatus, showed that lithium was present. Lime also could be detected in minute quantities.

Upon examining in his apparatus the spectrum produced by the residues of certain mineral waters of Germany, Bunsen observed the presence of two blue lines which did not belong to the spectra of any of the metals with which he was acquainted. He investigated this further, and at last discovered that they were due to the presence of a new alkali metal, to which he gave the name of cæsium, which existed in such minute quantities that twenty tons weight of water had to be evaporated down in order to obtain 100 grains of the substance. A specimen of the bi-tartrate of cæsium was exhibited to the meeting, and the colour which it imparted to the flame was shown.

The lecturer next proceeded to state that MM. Bunsen and Kirchhoff were engaged in researches by which they hoped to be able to extend this analytical method so as to include all metals. They had satisfied themselves that some of the rarest metals—metals which perhaps no one present had ever seen, or was likely to see, could be quickly and certainly detected in this manner.

The second part of the lecture was devoted to an account of the way in which they had partially found out the constitution of the sun's atmosphere. We need do no more than give a very brief resumé of this part, as a week or two ago we gave, in our "Scientific Gossip," a full abstract of these important researches of Kirchhoff. By means of a comparison of the solar spectrum with those produced by certain of the metals, it was found that for every bright line in the artificial spectra there was a corresponding dark line in the solar spectrum; and owing to the phenomena of the reversion of these bright lines when a brighter light was present behind the coloured flame, the conclusion was drawn that the light from the solid body of the sun gave a continuous spectrum, in which there were no lines, but that owing to the presence in the sun's atmosphere of the metal sodium, a *reversed* spectrum of the latter metal was produced, and the fixed line D was caused. In the same manner the presence in the solar atmosphere of iron, magnesium, nickel, and chromium has been proved. "If we could see," says Kirchhoff, "the spectrum of the solar atmosphere itself without that of the solid body, we should see in it the bright lines which characterise the metals which the atmosphere contains;" the more intense luminosity of the internal core does not, however, permit the spectrum of the solar atmosphere to become apparent, it is reversed, and those lines which would otherwise be luminous are rendered dark.

In conclusion, the lecturer remarked that these researches announced the birth of a new terrestrial and stellar chemistry, the developments of which it would be impossible to foresee.

REMARKS ON MR. CRAMB'S PAPER "ON TESTING USED SILVER BATHS," &c.

BY C. JABEZ HUGHES.*

[A few words of explanation are necessary in connection with the following remarks, as they are largely of a personal nature, and as the article which called them forth was not published in our columns. We give the paper *just as it was read* at the meeting, where it elicited much sympathy and applause: and we do so the rather, because in the organ of the society, for reasons we are not called upon to discuss, it was published in an altered, and, as Mr. Hughes conceives, an emasculated form. At the meeting in question, Mr. Hughes prefaced his remarks by observing that such a paper was altogether foreign to his habits and feelings, and regretted that the necessity for severe language was forced upon him; observing that nothing but the manifest *malus animus* of the attack upon himself, and the importance of interposing a severe check upon such productions, could have induced him to bring such a paper before the society.]

SINCE our last meeting, at which I read a paper on estimating the amount of silver in the nitrate baths, &c., another one in reply has been read by a Mr. John Cramb, of Glasgow, in

* Read at the Meeting of the North London Photographic Society, on Wednesday, 27th February, 1861.

which he alludes to experiments made by his brother, somewhat similar to those undertaken by Mr. Simpson and myself, the results of which are considerably different to our own. So far then we have two series of recorded experiments on the same subject, each tending to a different conclusion. This is unsatisfactory; for either one or the other, or possibly both, may be wrong. A re-examination of the subject is obviously suggested; and I am sure you will be gratified when I inform you that it is now being done, by gentlemen whose names will be a guarantee both of the accuracy of their results and their ability for the task, and that at our next meeting I hope to lay before you an interesting report, from which we may deduce safe conclusions, not only on the question in dispute, but on kindred points affecting the theory and practice of photographic printing.

For my own part I have no object to serve but the elucidation of truth, and its practical application to daily wants; and if it shall occur that the views I have expressed are not substantiated, when tested on a wider basis, I shall have pleasure in being set right, and shall cheerfully embrace the new views; for, after all, better men than I have committed themselves to positions which enlarged experience has not allowed them to maintain.

Awaiting therefore, respectfully but anxiously, the advent of this trustworthy information, I would leave the matter, were it not for the arrogant and insulting tone in which this Mr. Cramb has chosen to couch his comments on my paper, and I would pass them over with the contempt they merit, were it not that my silence might be misconstrued.

That he should dissent from my views was quite reasonable, for if we all agreed there would be no discussion; and that he should endeavour to show me where he supposed I was in error, was not only allowable, but highly commendable; but there is a proper and courteous method of doing this, which to the credit of photographers is rarely departed from. What particular immunity this person claims that he should be an exception, I cannot surmise, unless it be that this being his first paper addressed to any photographic society, he is unaware of the amenities required, even though they be not otherwise habitual. For my own part, I am always too happy to be taught; but I can never submit to be bullied: and while bowing with submission to any one who will point out my faults, and thanking them for the act, I distinctly deny them the right to do it in offensive language. But, right or wrong, I claim to be treated with ordinary courtesy and respect, and if, in the present instance, I somewhat depart from this course, it is to show this ill-mannered person that in criticising papers read before societies he must endeavour to acquire the habits of a gentleman, and that ebullitions of jaundiced and splenetic feeling will not be tolerated.

The whole communication breathes an air of self-satisfied egotism. I do not propose to follow him through his rambling address, the whole purpose of which appears to be to pervert and distort my views, and will only remark on the experiments themselves. They are based on the principle of inferring the amount of nitrate of silver in a solution from the quantity of a standard solution of chloride of sodium required to cause complete precipitation. In the use of this method I pointed out many sources of error. These experimenters have adopted one of these sources, viz., using only a fluid drachm to estimate the quantity in an ounce of solution, whereby an error becomes magnified eight times.

What means, if any, were taken to ascertain the accuracy of the drachm measure, are not explained. As many of the bath solutions examined were very concentrated, the error of a few minims either way, especially when multiplied by eight, is very grave.

Again, as the results of this method are obtained by indirect, not direct experiment, it is of the greatest importance that as a collateral check, a solution of *known strength* should be tested in the first instance. This was done by Mr. Simpson and myself; but these parties, in the pleuitude of their confidence, did not seem to think it necessary.

They must needs make a blunder in the equivalent weight of chloride of sodium, taking 60 instead of 58.5. This alone makes an error in all their calculations of aboat 1 grain in 40, or $2\frac{1}{2}$ per cent.

The result obtained from Mr. Bowman's collodion bath is so hostile to general experience, that that alone is enough to throw doubt on all their figures.

Why was the hydrometer tried on collodion baths at all, seeing that I more than once distinctly stated that it was not suited for them? Yet in their pompous array of figures they parade no less than *five* collodion baths.

It may be remembered that this Mr. Cramb had already condemned this instrument, confessing in the same breath that he had never tried it, a mode of proceeding not calculated to favourably prepossess one as to his impartiality as a judge, and certainly the contrary of what is adopted by the usual investigators of "chemical and hydrostatical science," about which he talks so complacently. Having established his conclusions to his own satisfaction, he should, when he selects his facts and adduces his figures, bring some indepeudent third party as a voucher, being himself far from an unexceptionable witness in his own case; but this confirmatory evidence is not supplied, and I therefore dismiss these unverified figures.

I have not attempted to reply at large to this person's paper, for after all the point in dispute is not of argument but fact, and as the question must be re-opened shortly, we may patiently wait. My main object has been to resent the insolent tone in which it is written; and in dismissing this provincial cynic, I trust when he next makes his appearance it will be with a more modest and becoming deportment, and that in alluding to persons with whom he may disagree, he will make an effort to use respectful language.

A NEW METHOD OF PREPARING PURE NITRATE OF SILVER FROM METALLIC SILVER ALLOYED WITH COPPER.

BY THOMAS A. BARBER.*

One of the simplest plans for recovering silver from an old bath is that of immersing a piece of copper, slightly acidifying the liquor, and leaving it until the whole of the nitrate is decomposed, and the silver falls in a metallic powder. In this case, however, the product is contaminated with copper, from which no amount of washing will free it.

My method of proceeding is this:—After well washing and drying the precipitate, I add carbonate of soda, or borax, and fuse it in a crucible, by which a part of the copper is eliminated. It is then poured out into cold water, bringing it into a granular and manageable form.

The solution of the silver in nitric acid is effected in the usual manner; but evaporation is carried on until the resulting mass begins to fuse, so as to drive off the excess of acid.

The salt is then rubbed in a mortar with a little oxide of silver, distilled water added, and the whole boiled. The oxide of silver displaces the copper, which falls as an oxide, and is separated by filtration, together with any excess of oxide of silver.

The liquor is then a solution of pure nitrate of silver, containing a small amount of oxide of silver, which must be neutralised by the addition of nitric acid, if evaporated for crystals, or by acetic acid, if transformed into a negative bath.

I fuse the silver, and afterwards the salt, in order to economise the use of the oxide, otherwise there can be no reason why the pulverulent silver should not be converted at once into a nitrate; for the oxide will rectify a solution containing both copper and acid—in fact, nitrate of copper may by the same means be converted into nitrate of silver.

The difficulty in this process is, to arrive at the proper quantity of oxide to be used without wasting it. This may

* Read at a meeting of the North London Photographic Association, February 27, 1861.

be ascertained by testing portions of the boiling solution with ammonia, and adding the oxide gradually, till every trace of copper has disappeared.

The method generally recommended to get rid of the copper, is to fuse the mass until the nitrate undergoes decomposition. The nitric acid is driven off, and oxide of copper remains; but the high temperature necessary for this operation involves the danger of forming nitrite.

Another plan has lately come under my notice. It is to wash the deposited metallic silver with weak hydrochloric acid, and then with ammonia. I have tried the experiment, but did not find it succeed; copper was still left, and chloride of silver formed.

If nitrate of potash be preferred in place of nitrate of copper, it may be readily effected by dropping into the boiling solution some caustic potash. The product will then be contaminated with nitrate of potash instead of nitrate of copper.

I give my method more as a chemical fact than as a useful addition to photographic operations; for I have long held the opinion that nitrate of copper is no bar to the working of nitrate of silver, and this Mr. Taylor, at the Photographic Society of Scotland proved to be the fact.

Most of our baths contain potassium, cadmium, ammonium, and very likely calcium, sodium, &c.; and why object to cuprum? The salts of this metal, are. I believe, just as free from actinic action as the others. Still it is of some service, and no little pleasure, to deal with a genuine article.

ON ORGANIC MATTER IN THE EXCITING BATH.

BY THOMAS A. BARBER.*

Amongst the many causes of failure attributed to the exciting bath is one which has struck me as being somewhat singular —that of the nitrate of silver having been wrapped in paper—for if organic matter is imparted by this means, what must be the effect of its solution running through filtering paper? Certainly one is sized and the other not, but in order to contaminate the nitrate, the surface of the paper must be abraded, instead of the silver being left on or in the surface of the paper, which I am inclined to believe is the fact

To elucidate the subject, I produce three bottles of solution of nitrate of silver, 30 grains to the ounce, the first is alkaline (*i. e.* saturated with oxide of silver) the second neutral, and the third acid, each containing a slip of demy paper such as is ordinarily used for wrapping up nitrate of silver, and which have had some days exposure to light; it will be observed that in neither case is the solution darkened, nor is there any deposit of organic matter, which might have been expected, had the solutions taken up matter of an injurious tendency, or affected by the agency of light. The papers assumed their blackness in the following order, the alkaline first, then the neutral, and lastly the acid.

A much more likely source of error lies, I think, with the distilled water. Here are three bottles filled with distilled water, that has been kept some considerable time. To each I have added nitrate of silver 1 grain to the ounce, alkaline, neutral, and acid, and exposed them to the light; the one containing the alkaline has crusted the impurities on the bottle, leaving the water colourless; the neutral is dark and opaque; the acid is bright and coloured.

I have three more, part of a carboy fresh from the wholesale druggist (an indirect but general source from whence most photographers derive their supply) treated in the same manner. It will be observed that the alkaline has done its work, the neutral is bright and coloured, whilst the acid gives no evidence of presence of organic matter.

Here is a sample obtained from one of our oldest established chemists, but like every other that I have tried, it will not stand the test of a weak solution of alkaline nitrate of silver. I use weak solutions, because I find them give much more satisfactory results. Observe the difference in the colour of the same water acted upon by 1 grain and 30 grains to the ounce.

It should be understood that distilled water can never be relied upon for purity. That which comes over first (some say the first third) ought to be thrown away, nor ought the still to be used for any other purpose. Waste steam from an engine is not unfrequently turned to account. Water containing no inorganic matter suffices for almost all chemical operations, but if it be a *sine qua non* in photography that it contain no organic matter, then recourse must be had to some means for testing its presence, and such is the avidity with which the alkaline nitrate of silver seizes all impurities, that I have no hesitation in saying that if a newly made bath be dosed with oxide and exposed to the light, it is immaterial whether it be made with distilled water or not.

Proceedings of Societies.

London Photographic Society.

The monthly meeting of the Photographic Society was held at King's College on the evening of Tuesday, March 5th. F. Bedford, Esq., in the chair.

After the minutes of the previous meeting were read and confirmed, the following gentlemen were elected members of the society:—Thomas Sutton, Esq., B.A., Lecturer on Photography at King's College; the Hon. Maurice Wingfield; R. K. Dick, Esq.; Capt. James Buchanan, Madras; J. E. Norris, Esq.; L. Musgrave, Esq.; R. W. Hall, Esq.

Several specimens of prints were exhibited by Messrs. Vernon Heath, Fry, and others; also a large folding camera by the first-named gentleman.

Mr. Spiller read a paper describing his dessicating box, in which quicklime is used, instead of chloride of calcium, the usual dessicating agent applied to such purposes. The box was exhibited together with several excellent prints upon paper, which had been kept in the box several weeks after sensitizing. He was in the habit of using quarter sheets of paper which, after sensitizing and drying, were just thrown loosely into the box, curled up as they were. He had found on weighing a sheet of paper after coming from the box in its dry state, and then again after it had been exposed to the atmosphere to regain its ordinary hygroscopic condition, that each quarter sheet gained seven grains of moisture, weighing eighty grains when quite dessicated, and eighty-seven in its ordinary state. A full account of this drying box, communicated by Mr. Spiller, will be found at page 256 of the Photographic News, vol. iv.

Mr. Spiller also showed some varnished negatives in which the film was very much cracked, which he attributed to damp and the severe changes of temperature during the winter. He suggested the adaptation of the principle of his drying-box to common plate boxes for sensitive dry plates, and for valuable varnished negatives.

After a few remarks from the Chairman on the importance of the subject,

Mr. Shadbolt asked Mr. Spiller if the lime would have sufficient absorptive power to dry albumenized plates.

Mr. Spiller thought it would draw away the surface moisture.

Mr. Vernon Heath remarked that Marion's preservative case struck him as more convenient than the one before them, and paper might be kept in it for three months without spoiling. Would Mr. Spiller state the peculiar advantages of his own box over others.

Mr. Spiller remarked, in regard to the question of size, his could be made smaller if necessary. He had it made its present size and shape in order to admit of the sheets being thrown in just rolled up as they had dried. He did not claim anything especially new in this box. The dessicating powers of quicklime were well known before, but it had not been applied before to this purpose; and he thought it had some advantages over chloride of calcium, which was generally used.

Mr. Shadbolt remarked, that an essential difference existed in the fact that Marion's case was nominally a secret, whilst all the details of this were clearly explained; and a considerable difference in cost would necessarily result. He thought if, instead of deal, lead were used, and filled with sulphuric acid, a valuable drying box for dry plates might be made.

Mr. Hughes thought, one reason why drying or preservative boxes did not come into general use, was that the paper was not considered so good after keeping in them. There was a difficulty in getting the prints to tone well; they did not readily pass beyond the brown stage into that rich purple which was desired. He saw two gentlemen in the room who had some practical knowledge on this subject, if they would give the meeting their experience; he referred to Mr. Eliot and Mr. Fry.

Mr. Samuel Fry said, that there was a picture of his on the table, to which he would call attention, which had been kept a month after printing before toning, having been accidentally put away with some sensitive paper. It subsequently toned very well. His plan of preserving sensitive paper was a very simple one, but he found it perfectly efficient. He had a tall glass bottle, such as confectioners use; it was about 30 inches high, and had a tight-fitting glass lid. He covered the bottom with common salt, well dried, to a depth of about an inch and a half, and covered this with a piece of card. He sensitized the paper in whole sheets, and, after drying, placed them in this bottle folded round inside. He found no difficulty with sheets so kept for a few weeks or even longer.

Mr. F. G. Eliot said Mr. Sedgefield had one of Marion's preservative cases. He found them, when three or four quires of excited paper were placed in it, that the few sheets at the top and bottom were all right, but as for the whole of the remainder the effect was the same as if there had been no chloride of calcium present.

The Chairman remarked that too much atmospheric air was enclosed with the quantity of paper to render the cholride of calcium available.

Mr. Fry described a drying box he used for sensitive plates. It was a double tin box, with about three-quarters of an inch between the outer and inner portions. This was filled with hot water, and readily dried the plates.

Mr. Malone remarked that in reference to the chloride of calcium being found of no use in some cases, it was an important point to ascertain how long it had been used. It might have been so long in use as to have become fully charged with moisture. Regarding Mr. Spiller's box, the object of introducing it was quite clear. It simply came before them as a good working tool, which could be made by any ordinary workman, and which photographers could have made for themselves at a trifling expense. Chloride of calcium was more greedy of moisture than the quick lime, and if, therefore, the extreme dessication effected, were an evil, lime would be best of the two. As for sulphuric acid it was more greedy of moisture still, and would therefore be worse in that respect, whilst if the vessel containing it were upset, it would scarcely be necessary to describe the consequences. Mr. Spiller's was, he thought, therefore, the best and cheapest contrivance. But as for the thiug itself, he had no liking for the plan of preserving paper. To get the best results the paper should be excited, dried, and used as quickly as possible. If it could be shown that preserving the paper gave inferior results, he thought all questions of convenience should be put aside, and printers must rise early enough in the morning to prepare each day's paper. If keeping a short time were necessary, he remembered it used to be customary just to place the sheets in a pressure frame and screw them down to prevent the action of the atmosphere. Perhaps the adoption of such a plan might solve the whole question.

Mr. Eliot said that in the case to which he had referred, care was taken that the chloride of calcium was not charged with moisture; but that the sheets being packed close together no action was exercised, except on a few outside sheets. On this account he admired Mr. Spiller's box; it admitted of the sheets being thrown in quite, loosely iustead of tightly pressed together.

Mr. Spiller remarked that it was very easy to ascertain when the lime had lost its dessicating power. When it was slaked it fell into powder; so long, therefore, as there was a lump left its, drying powers remained.

A desultory conversation on the causes of cracking in the varnished negative film ensued, in which the Chairman, Dr. Diamond, Mr. Spiller, Mr. Fry, Mr. Thomas, and others, took part. A general opinion prevailed that damp and changes of temperature were the chief causes of such cracks.

Dr. Diamond exhibited some prints which had continued perfectly good for some years until recently they were hung in a room against one of the outside walls, and they had rapidly faded. Others of the same lot of prints which hung against the inner walls of the room were not affected.

Mr. Malone remarked that we had not yet sufficient knowledge as to the means of keeping photographs from fading, even when toned with gold, and the sooner it was admitted the better. It was impossible to keep pictures entirely free from damp and from tho influencer of sulphuretting vapours, and under existing circumstances it was merely violating a natural law to hope for their permanency. He had always insisted on this. Even with the most careful washing, it was uncertain. He had treated some with boiling distilled water which had nevertheless faded.

Mr. Heath rose to order. He wished to know what was the subject before the meeting, which he had thought was the use of drying-boxes.

Mr. Malone was merely pursuing the subject introduced by Dr. Diamond.

Mr. Sedgwick thought Mr. Malone was quite in order.

The Chairman said it was perhaps a little digression from tho original subject, but had become so by a most natural transition, and the subject was a most interesting oue.

Mr. Malone would return to the question of cracked negative films, which was connected with the drying boxes. He thought that tho varnish in many of these cases had been blamed unduly. Why might it not be some peculiarity in the collodion, or some difference in the contractible conditions of the collodion film and the varnish.

Mr. H. G. Bohn, referring to the faded prints shown by Dr. Diamond, said it was simply caused by mildew from a damp lime wall. Any ordinary picture, not a photograph, would probably have suffered just in the same way under the same circumstances.

The Chairman now intimated that the discussion on Mr. Hughes's paper "On Albumenized Paper," which was adjourned at last meeting, would be resumed.

The Secretary read a letter from Mr. Hardwich, in which he intimated his fear that the difficulties in the way of getting English paper-makers to enter into all the experiments which would be necessary, would be very great, unless we could assure them of a demand sufficient to repay the trouble.

Mr. Bohn said, one of the largest paper-makers, a gentleman who had two mills at Maidstone, was sitting by his side, and could probably give some information on the subject.

Mr. Busbridge, of Maidstone paper mills, said he had read with great interest the account of the last meeting. He felt a double interest in the matter, arising from his interest in photography and his iuterest as a paper-maker. He must confess he had looked with great jealousy on the idea that they could not as Englishmen make paper in all respects equal to that made in France or Germany. He felt sure they, as English paper-makers, had only to know exactly what was wanted, and they could accomplish all that was required. He had for some months past given the subject some attention. So far as he at present understood it, it was his impression that a paper composed of one uniform fibre would be desirable, so that there should be no mechanical differences of texture. If colour were of importance, they could give just the same tint as the French papers. What he wanted was, however, information of the exact requirements of the photographer, and he could assure them English makers would not be left behind in the production of all that was necessary.

Mr. Shadbolt referred to the preseuce of metallic spots as one of the great evils to be got rid of.

Mr. Malone had investigated the cause of these spots, and ascertained that they proceeded from pins, buttons, &c., remaining in the rags, as the makers stated that it would not pay to pick over every inch of rag. He had no wish to discourage Mr. Busbridge; but it was important that he should know that he would have to enter into a vast number of experiments, as there were other considerations beyond the mere production of a good uniform texture of paper, such as the iufluence on toning of different-sizing agents, &c. He thought it right to say, also, that if they as photographers assisted a maker with information as to what was wanted, he must be perfectly open in return, and have no trade secrets in the matter. He must be content with the advantage of having first hold of the market.

Mr. Busbridge said, that for photographic purposes they could give the necessary care to pick over the rags. so that there shold be no metallic particles. He was fully prepared to enter into the subject with spirit, and would esteem it as the blue ribbon of the society to succeed in producing what was required. Nothing would repay him so well, not even £ s. d., as the knowledge that he had fully succeeded in meeting their requirements.

Mr. Sebastian Davis thought it would be a valuable plan of taking advantage of Mr. Busbridge's desire to aid them, and enable them to give the best information to that gentleman, if gentlemen interested in the matter were supplied by Mr. Busbridge with samples of paper made from the most delicate linen rags, one without any size, one sized with starch, and another with gelatine. These could be printed and toned, and their results compared.

Mr. Fry suggested the importance of producing, if possible, a paper with sufficiently fine surface to render albumenizing unnecessary.

Mr. Thomas referred to the mordants used by paper-makers which might be injurious, as alum for instance, which contained sulphur, or at least sulphuric acid. They might be introducing the elements of decay into their pictures when they least expected it.

Mr. Busbridge said, that alum had both a preservative and a destructive action. Gelatine size would decompose if no alum were used, and it decompased if excess were used. He thought that probably the use of a pure gelatine size, and a very small quantity of alum would be found to answer the purpose of photographers.

Mr. Thomas referred to a formula for sizing given in "Ure's Dictionary," consisting of twelve parts of starch, and one part of resin dissolved by means of soda.

Mr. Malone thought they could not too emphatically admit that they were quite in the dark on this question. He remembered that in former experiments it was found that in some prints the size was not readily dissolved out of the paper, and these were found most permanent. It might be that this was due to the effect of alum, and it might he that they would require its operation. At present they did not know what that operation was; but it was by no means clear that it was injurious. Whatever size might be used, he was of opinion that better results would be obtained by introducing a portion of it into the pulp itself, so as to get a clear transparent texture right through as well as on the surface.

Dr. Diamond referred to the use of hyposulphite of soda in the manufacture of the best class of papers.

Mr. Busbridgr said, its use was by no means necessary or common. It was the exception, not the rule.

Mr. Malone said, that when he was on a visit to one of the Maidstone mills, he asked of what they made their paper, and was told of nothing but good rags and fresh hoofs for sizing. He received that statement in good faith; but as he had recently read in the *Comptes Rendus*, that sulphito of soda was used under the name of "anti-chlor.," to neutralize the action of the chlorine used in bleaching the paper, during the course of his visit he asked the question, if sulphite of soda were ever used, and it was then admitted it was, notwithstanding the former statement, that nothing but rags and fresh hoofs were used.

Mr. Busbridge remarked, that it was quite possible Mr. Malone was answered in good faith. He asked what they *made* their paper of, and it might never occur to them to speak of a chemical used for a specific purpose, but was not part of the manufacture of the paper. However, it was not necessary, and he would promise them to make a paper in which it should not be used. They should have a pure pulp made from a single fibre.

Mr. Heath thought it was a very satisfactory thing to know that an English manufacturer would undertake these experiments, and thought they might look for very satisfactory results. He had been deeply interested in reading the paper read by Mr. Hughes at the last meeting, and could not but think that he had struck a chord, which it would be well to sound at all times and seasons. He referred chiefly to the admitted negligence and carelessness in printing generally. It was not possible that greater injustice could be done to negatives than they had frequently received, and he believed that few persons were aware of the real capabilities of their negatives because they entrusted them to other people to print. Speaking for himself, he had sometimes taken many proofs before he discovered how good a picture a certain negative would yield. He was convinced that if the desire were once established to obtain all from a negative which it would yield, the custom would cease of giving negatives to persons who print by the acre. He wished it were well understood that there was such a thing as *cheapness* in printing any more than in any other department of the art. In regard to the question of permanency he had prints done by all processes, which remained permanent, and he now produced some prints from the "Pencil of Nature," which were done in 1845, and only one of them was at all faded and that only at the edge where it was mounted. Still he preferred the alkaline toning process. They knew better what they were about with it, and had the toning more under command. He used chloride of barium as the salting agent, and preferred it because of the warm tone he obtained with it, because he thought less was lost in the toning than when other chlorides were used. He used Saxe paper. He concluded by urging the importance of care in printing throughout, and especially in washing.

Mr. Malone, referring to the pictures from the "Pencil of Nature," remarked that in the one which had faded at the edge it was not the mounting which had caused that fading, but simply that the edge was first attacked by the atmosphere. These pictures furnished a singular illustration of how little was understood of the causes of permanency. They were printed in 1844, and had most of them remained permanent, and yet they only received about half an hour's washing. After fixing each print was put into a pan with two gallons of water, and about 25 prints would be washed in that water. After remaining about ten minutes in the first pan, the print was removed into another similar pan, and in ten minutes more to a third; each print in succession, until tho whole 25 were completed. So that six gallons of water washed the 25 prints of the size 9×7. That some portion of hyposulphite of soda remained in them there could be no doubt, as they toned darker when a hot iron was passed over them; and yet many of them were good now. It was a great misfortune, but the simple fact was we knew very little about it; we did not know to this day of what the image was formed, whether of metallic silver entangled with the fibre of the paper, or of suboxide of silver with organic matter. Knowing so little of what the picture itself really was, it was not surprising we knew so little of the sources of permanency or fading.

The Chairman thought the causes of many photographs fading was the culpable negligence and carelessness with which they were kept. He thought if tho same care were bestowed upon them as upon valuable drawings, tho cases of fading would be less frequent.

Mr. Davis asked if these pictures were printed by direct sunlight or diffused light, as he had an impression that direct sun-printing was favourable to permanency.

Mr. Malone said they were printed indiscriminately with just such light as the day might present.

Mr. Fry, referring to the difficulties experienced by some with the alkaline toning bath, remarked that different samples of paper required different treatment, and that the different formulæ, such as the use of the acetates, posphates, carbonates, &c., with the gold, offered facilities for this different treatment. He thought that every variety of paper would tone by one or other of theso formulæ. There was, however, another difficulty which printers had to deal with, and that was weak, poor negatives. In some cases it was utterly impossible to get a presentable print from some negatives without using the old bath, and he thought when reasonable care, and Lake Price's formula was used, permanent prints might be obtained.

Mr. Eliot stated that when using the alkaline toning bath with one sample of paper, he was unable to get anything but the most unsatisfactory results, until he tried the addition of citric acid, when the prints were immediately rich and brilliant. Subsequently on trying another paper, the *Rive* paper, he was compelled to abandon the use of citric acid, as it retarded toning seriously. It was manifestly necessary to adapt the toning formula to the especial requirements of the paper used.

Mr. Hughes was much gratified with tho interesting discussion to which his opening remarks had given rise. The subject was one of the most important and interesting which could come before them; it was impossible to over-rate it. It was the final object of all their other efforts. Photographically, it was the one question of the age; and indeed he did not think it was saying too much to remark, that he thought they could get up a case for a royal commission to investigate, with much more reason than existed for many such commissions. He had hoped to have elicited many more comparisons of practical experiences; the inquiry had, however, risen to a higher and more important issue, namely, the investigation of what he had become more convinced was at the bottom of all their troubles—the original nature of the paper itself. They had hitherto known nothing at all about it; and if the papers of foreign makers had in many instances answered their purpose best, it was not because foreign makers had listened to their requirements and met them; it was simply the accident of their peculiar method of manufacture. We had now, however, for the first time, the offer of assistance from gentlemen competent to deal with the question of the primitive paper itself. He had attempted to albumenize all kinds of papers, German, French, and English; he had prepared them and treated them throughout exactly in the same manner, and had obtained results the most dissimilar, all arising from the character of the primitive paper. The printing troubles have been unquestionably increased by the process of alkaline toning, and that simply because it more readily revealed the native badness of the paper, whilst the old process more frequently ignored it. But they had been dealing throughout with what they scarcely knew anything about. They talked of *Saxe* paper, but they really did not know what it was; of *Rive* paper, and they scarcely knew whether that was the name of a maker or a place, or indeed scarcely what it denoted, whilst some fancied it was something made within a few miles of London, and so called merely to deceive. Mr. Fry had referred to the influence of the various organic salts in toning different samples of paper. This was a question which, as yet, had received very little attention, and he would commend it to the consideration of intelligent printers to try the respective effects of the tartrates, the oxalates, the formiates, as well as the citrates and acetates, and the hundred other organic salts in connection with gold, in toning different samples of paper. Some allusion had been made to the fact that some prints by the old processes did stand. That was just one of the subtle allurements of his majesty Sulphur, he did sometimes leave a few safe. He had left some, it seemed, in 1844. And then when any of his votaries began to waver in their allegiance, he cried out in oracular tones, "This print was produced so and so many years ago, and is still unchanged; *therefore*, &c., &c." But examine carefully, and it would be found that whilst that one had stood out of a thousand, the other 999 had gone the way of all flesh, and of all photographs. Whereas, under the happy auspices of gold it would be found that whilst some few, through carelessness do undoubtedly fade, the report of after years would, he hoped, be that out of each hundred at least 90 had stood, and only 10 faded. Their weak point still was hypo. Whilst they fancied they had deposed his sulphur majesty, he still contrived, now and then, to do them a little harm. They used the hypo too often; they changed it too seldom; they were afraid of losing their tones, and thus they unconsciously went back to sulphur toning, again enthroning his mischievous majesty without knowing it. The great point was to get rid, if possible, of hypo as a fixing agent. It was surely possible. It was only the other day that this salt was discovered. Its discoverer, Sir Jon Herschell still lived. It was scarcely to be believed that if that had not been discovered something else would not have been found to take its place in photography; and he hoped to see the day when some other means would be found to dissolve out the chloride of silver from their prints as speedily and safely as it was done from their negatives, and without leaving a lurking danger behind.

The usual votes of thanks terminated the proceedings at a late hour.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting was held at Myddelton Hall, Islington, on the evening of Wednesday, the 27th ult. Mr. G. SHADBOLT in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were elected members of the Association:—Messrs. Rodgers, of Montrose; Shepherd, of Aldie; Stone, of Bethnal Green Road; and Scott, of the Priory, Tottenham.

Mr. BARBER then read a paper on "A New Method of Preparing Pure Nitrate of Silver from Metallic Silver Alloyed with Copper." (See p. 112.)

Mr. Barber exhibited specimens showing the nitrate in combination with copper, and after its purification.

The CHAIRMAN remarked, in reference to alleged photographic inaction of nitrate of copper, that he remembered Mr. Burnett had on one occasion made use of the salts of copper for the production of certain tints. This, he thought, showed that it was not wholly without action.

Mr. BARBER had prepared a bath with half a drachm of nitrate of copper present, with the same amount of silver, and then produced a good negative. He thought the action was very slight and unimportant, if it existed at all.

Mr. BARBER then then read some interesting remarks on "The Sources of Organic Matter in the Nitrate Bath." (See p. 113.) These remarks were strikingly illustrated by the production of bottles containing the solutions referred to.

After some conversation,

The CHAIRMAN produced, for the inspection of the meeting, the hydrometers to which he had referred at a previous meeting, as prepared by Negretti and Zambra, for ascertaining with considerable accuracy the specific gravity of a small quantity of fluid. One was for the testing of liquids lighter than water, and the other for liquids heavier than water. For use with silver solutions it would be necessary to multiply the figure registered by 6. A 30-grain solution of silver, illustrating Mr. Barber's experiments, was tested, and and the instrument was found to give exact results.

Mr. C. JABEZ HUGHES then read "Some Remarks on Mr. Cramb's Paper on Testing Used Silver Baths." (See p. 111.) He prefaced the paper by remarking that every gentleman present would bear him witness that the remarks he was about to make were entirely foreign to his usual manner and spirit. He had, however, felt it his duty to offer a prompt and energetic protest against a paper so unusual in character and uncalled for as Mr. Cramb's. If attacks like the one in question were permitted without check and marked censure, they would have the effect of entirely deterring some persons from taking part in photographic meetings. Regarding the subject, he might state that further experiments of a very delicate and satisfactory character were in progress, and were in the hands of gentlemen in whom they all felt perfect confidence, and would be brought under attention at a subsequent meeting. Mr. Hughes then proceeded to read his remarks, which were received with marked sympathy and applause.

Mr. DAWSON said he had intended to have read a paper on this subject, and to have made some remarks on the extraordinary performances of this same Bombastes Furioso of the north, but as Mr. Hughes himself had taken up the subject, he thought he could not leave it in better hands; he would, however, read one or two extracts on some experiments. At the last meeting, after the reading of Mr. Hughes's excellent practical paper, it would be remembered, he (Mr. Dawson) expressed a very strong doubt, founded on theoretical principles, whether even in old paper exciting baths, the hydrometer test would give an approximate estimate of the actual amount of silver present, on account of the large amount of other nitrates necessarily accumulating from the double decomposition. Mr. Hughes replied that such an accumulation did practically take place, but to a very limited extent. Since then, he, Mr. Dawson, had made several very careful analyses of some old baths he had by him. Two examples, with the permission of the society, he would read from his laboratory memoranda. He selected these two because the baths had been long in use, only by himself, so that he knew their history, and they were made from and kept up by pure nitrate of silver. The results he would give were the mean of three analysis, which did not vary more than one-fifth of a grain. The history of the bath analysed was this:—It was an old positive paper bath, about ten months old, and was originally three quarts of a 90-grain solution; kaolin sufficient to discharge the colour as it formed, was deposited in the stock bottle, and allowed to remain; after each occasion of its being used, the flat exciting dish and the drop-catchers were rinsed out with distilled water, which was poured into the stock bottle along with 240 or more grains nitrate of silver; the quantity of solution was now reduced to about one quart. The specific gravity at 60° was 1·152, equal to about 83 grains of nitrate of silver to a fluid ounce. As the temperature was raised, the results were—

Spec. grav. at		80°=1·148=	about	81	grs. of	nitrate to	fluid oz.
"	"	90°=1·146=	"	80	"	"	"
"	"	120°=1·140=	"	78	"	"	"
"	"	140 =1·136=	"	76	"	"	"

The ratio of decrease by increased temperature would perhaps be more uniform if it were possible to perform the experiments with perfect accuracy. In the next experiment he took one fluid ounce of this solution, and precipitated it by pure hydrochloric acid, it yielded 67·2 grains chloride of silver, equivalent to 79·6 grains nitrate of silver present in each oz. of the bath. This showed the specific gravity test at 60°, only gave an error of three or four grains. The filtered liquor on evaporation, and after all the nitric and excess of hydrochloric acid had been expelled, left as residue 7·6 grains, consisting of 5·2 grains soluble nitrate, and 2·4 grains organic matter, apparently combined in some way with carbonic acid—but he did not investigate its nature further. The chloride of silver and residue was, as he had said, the mean of three analyses. The organic matter was the mean of two. A test solution of 66 grains pure dried chloride of sodium in 24 ounces distilled water, shewed always precisely 80 grains to the ounce. This slight discrepancy between the perhaps more exact, but certainly more tedious, process of precipitation by pure hydrochloric acid, and the latter modification of Gay Lussac's method, no doubt arose from the difficulty of expelling all the water from the salt, and of measuring out such a large quantity of water precisely. From the quantity of nitrate of silver added to this bath, and from its frequent use, he should certainly have expected to find a very much larger proportion of other nitrates. The equivalent number of nitrate of soda being 84·97, or, in round numbers, 85, it followed that for every two grains of nitrate of silver abstracted by decomposition, one grain of nitrate of soda ought to be left in the bath. This seemed not to be the case in practice, and although the nitrates must be formed, they were, it would seem, partly retained by the albumen or the paper, or taken away by some means not accounted for. He next analysed an old collodion bath. Its history was this:—It was made about the beginning of June, 1860, of the strength of 35 grains to the ounce—40 ounces being made up, and the bath holding about 18 ounces; it was used occasionally during that month, almost daily during July, and pretty frequently since; it has travelled and been knocked about over the wilds of Scotland; yielded upwards of 200 stereoscopic negatives, and lain for four months in a warm room in an open gutta-percha bath; no water has been added, but occasionally crystals of nitrate as it seemed to require them. The specific gravity at 60° was 1·050, showing about 26 grains to the ounce. The analysis by hydrochloric acid gave 26·5 grains chloride of silver, corresponding to 31·39 grains nitrate of silver to the fluid ounce. The analysis by a standard solution of chloride of sodium showed 32 grains. The evaporated liquid yielded 3·2 grains soluble nitrates, ·9 grain organic matter. This organic matter was so light that after drying it floated in water. Its nature he did not determine. He did not say that these experiments entirely settled the question; but the experiments were performed with great care, and certainly seemed to indicate that for all practical purposes connected with the printing-bath the hydrometer gave a sufficient approximation to correct results. As regarded collodion baths it was admitted the hydrometer was not of much use, as the accumulation of alcohol and ether must seriously affect specific gravity. Even after attempting to expel these spirits by evaporation it could not be relied upon, as they were not so easily expelled as might be imagined. After boiling down a bath on one occasion until it was nearly all evaporated, it still retained the smell of ether. The ether could undoubtedly be driven off; but not until nearly all the water was at the same time evaporated. He repeated again, that these experiments were but the beginning of others he intended to make.

The Chairman remarked that the subject was in good hands, and would be examined in several directions by men who were throughly competent to do it justice. The influence of the coagulated albumen in retaining the nitrates had been suggested at the last meeting by Mr. Simpson, and Mr. Dawson's experiments seemed to confirm the idea.

Mr. Moens remarked that Demetrius Constantine, of Athens, who was a good authority, constantly used the hydrometer.

Mr. Hughes said he had placed in Mr. Dawson's hands portions of some of the baths which Mr. Cramb had tested. Mr. Dawson knew nothing of what they were, nor whose they were, so that the results which he arrived at could not be influenced by anything that had been already done.

A conversation then followed on the manifest temper shown in Mr. Cramb's paper, after which the subject dropped.

The Chairman called attention to a reproduction presented to the society's portfolio by Mr. Lander.

Mr. Mainwaring offered to the society for the portfolio, a series of very fine photographs of prize flowers.

The remainder of the evening was employed in the nomination of the various officers and gentlemen of the committee for election at the general meeting next month.

After the usual votes of thanks the proceedings terminated.

City of Glasgow and West of Scotland Photographic Society.

[We extract the following from the organ of the society. We may remark that we are a little puzzled to understand from the reports the exact tone of the proceedings, as in the last report Mr. Stuart is described as expressing the highest satisfaction with Mr. Cramb's experiments, whereas we find the same gentleman at the adjourned meeting denying the accuracy of the report, and prepared with a series of carefully conducted chemical experiments in refutation of Mr. Cramb's experiments.

An adjourned meeting of this society was held on Thursday evening the 14th ult.,—Mr. J. Stuart, one of the Vice-Presidents, in the chair.

The Secretary read a letter from A. Claudet, Esq., in reply to the intimation of his having been elected an honorary member of the society.

Mr. James Cramb then read some "Notes on the Hyposulphites of Silver," and illustrated his remarks by the performance of some experiments.

Mr. Stuart then left the chair for the purpose of joining in the discussion on the hydrometer silver mèter question, adjourned from last meeting. Mr. Duncan Brown occupied the chair during the rest of the evening.

Mr. Stuart reported the results of some experiments made by himself and Messrs. Kibble and Macnab on one occasion, and by himself and Messrs. Macnab and Bowman on another occasion. He (Mr. Stuart) said they had not adopted the plan pointed out by Mr. Cramb of testing the bath, but had taken the true chemical plan of converting the whole of the silver in the baths into the chloride: and to prove the perfection of their analysis they had also made some nitrate from known pure silver. His own bath, they found by their plan of testing contained 88 grains of nitrate; Mr. M'Farlane's 92¼ grains of nitrate; Mr. Macnab's 36¾ grains of nitrate to the ounce. The argentometer obtained from Mr. Spencer, at 60° temperature in a standard solution known to contain 47½ grains to the ounce, stood at 44, or 3½ grains to the ounce of error. In a 30-grain standard solution it was quite correct. This meter indicated 92 grains in Mr. Stuart's bath, and 99 in Mr. M'Farlane's. He (Mr. Stuart) said he mentioned the bare facts—they could draw their own conclusions. On the question of temperature he had to report as follows:—The argentometer showed a variation of 1½ grain to the ounce for *ten* degrees of rise of temperature from 60° to 70°, and from 70° to 80°.

Mr. John Cramb said he would, with the leave of the meeting, attempt to show how much Mr. Stuart's facts proved in this question. He would first correct an error Mr. Stuart had evidently fallen into. The plan of analysis pursued by Mr. Stuart and his friends had been pointed out in his (Mr. Cramb's) paper read at the previous meeting, and the phrase, "true chemical plan," seemed to him simply absurd—as it was quite as consistent with the principles of chemistry to estimate the amount of silver in a solution by the amount of chloride required to precipitate all the silver, as to weigh the amount of chloride precipitated, and so judge of the quantity of nitrate of silver contained in the solution tested. The objection to the later plan was pointed out at the last meeting—its impracticability for photographers in their daily practice. He would beg the members to observe that the results obtained by Mr. Stuart and his friends were thus far confirmatory of the results laid before the society at the last meeting—that in all Mr. Stuart's trials the result was higher, and in a pretty constant ratio, which would lead him to suspect some constant source of error, either in the instruments employed or in the manner of using them. He (Mr. Cramb) at this point insisted on the injudiciousness of citing Mr. Kibble as a guarantee that all had been correctly done. Mr. Kibble was not present, and he, for himself, would not care to animadvert on the statements of a gentlemen which they only had at second-hand.

Mr. Cramb was proceeding to comment on the statements of Mr. Stuart on the effect of temperature, made at the last meeting and in his present report, when Mr. Stuart denied the accuracy of the report, attributing to him to have said that a difference of *one grain* of silver of error to each *degree* of temperature above or below 60° would be indicated by the argentometer.

Mr. Cramb, as secretary, appealed to the meeting whether he had not given a correct report, and it was unanimously declared to be correct.

Mr. Stuart had not said it was a grain to the ounce.

Mr. Cramb said Mr. Stuart was on the horns of a dilemma: his choice was the longest and the sharpest horn.

Mr. James Cramb, pointing to the argentometer said to have been used, remarked that it was impossible to measure half-grains by such an instrument; and, as it had been confessed to be inaccurately divided, he was astonished that gentlemen would use such an instrument in any careful investigation. He simply wished to say further, that the grain and a half per ten degrees of additional temperature, though far below Mr. Stuart's former estimate, was yet much in advance of truth; but in such a matter he would rather show the society the result than tell them of what he had obtained by himself.

Mr. John Cramb said the results given by Mr. Stuart on the specific gravity question were utterly valueless: he (Mr. Stuart) had not tried the bath, except by a hydrometer which he himself had said was erroneously graduated. Why not take the specific gravity bottle, as his (Mr. Cramb's) brother had done?

Mr. Macnab referred to the fact that they made their nitrate from pure metallic silver.

Mr. James Cramb asked how much solution was operated on from each bath?

Mr. Stuart said one ounce of each.

Mr. James Cramb asked what kind of measure they used in measuring the quantity?

Mr. Stuart held up a common conical two-ounce measure.

Mr. James Cramb said it was unwise to talk of careful analysis, and use such a measure, where, from the extent of surface, error would be so imminent. He considered the whole affair as unreliable, and totally unworthy of any one making pretension to scientific accuracy. Analytical chemists used an accurately graduated measuring bottle, which he described.

Mr. John Cramb said he thought it would have been courteous if he or his brother had been invited to be present at the re-testing of baths which they had tested; but as the gentlemen who had reported the results that evening had not thought so, and as the subject seemed by their statements not so satisfactorily settled as it could be, he would propose that the society appoint a small committee to investigate fully the whole question. He still thought it a very small matter, and unworthy of the whole society spending an entire night upon it again; but a report by a committee would not take up much of the society's time.

Mr. Ewing said he thought that the subject had been sufficiently discussed, and he would move that it be now dropped.

Mr. A. Robertson seconded Mr. Ewing's motion.

Mr. Cramb's motion for a committee failed for want of a seconder.

A short discussion followed on the graduating of dropping tubes, &c.

Chorlton Photographic Association.

The ordinary meeting of this Association was held on Wednesday the 13th ult.,—Mr. W. Griffiths in the chair.

As there was no paper, the proceedings were of a desultory and conversational character.

Mr. Wardley said, in answer to a question on transparencies, he was decidedly in favour of taking them by contact on dry plates with artificial light, he had invariably found that pictures taken on wet collodion were wanting in that sharpness and definition which printing by contact on dry plates always gave. Any of the numerous dry processes might be used, but he gave the preference to the raspberry syrup, because the tones produced by it were agreeable and pleasing when viewed in the stereoscope, and also because the beautiful softness and semi-transparency of the shadows which it gave made it particularly well adapted for pictures intended to be used in the lantern; there were certainly the usual difficulties attending all dry processes to be overcome, but they were not such as might not be easily got over by careful manipulation. The principal and only important ones were the liability of the sensitive film to become attached to the negative while in the pressure frame, in consequence of the adhesive nature of the preservative coating; and the next was the tendency sometimes in the collodion to split up or leave the glass during the development or the subsequent fixing. The first might be readily avoided by well drying the sensitive plate before putting it in the printing frame; and the second could generally be overcome, if not entirely obviated, by coating the plate, either wholly or partially, with albumen or gelatine, previous to the application of the collodion.

The Chairman thought that such a use of it must inevitably lead to a discolouration of the bath.

Mr. Hooper said, from the slight experience he had had of it, he was inclined to the view that no deterioration of the bath took place.

Mr. Wardley said it was impossible to use albumen in the manner stated, or even to the extent of a quarter of an inch all round the edge of the plate, without the sensitive bath becoming after a time discoloured and unfit for ordinary wet negative pictures. The coating with gelatine was not liable to the same objections, but greater care was necessary in their preparation, particularly as respects keeping them free from dust and damp.

The Chairman said he did not altogether agree with Mr. Wardley, that the best mode of taking transparencies was by contact, and not through the camera; he believed that, by proper arrangement of lenses and stops, the latter method would be found to present fewer difficulties, with results equally satisfactory as respects sharpness and good definition.

A lengthened discussion then took place on the toning of positive prints by the alkaline chloride of gold. After which

The Chairman made some observations on uranium printing. From the permanency as well as the occasional beauty of its results, he thought a great deal more might be made of it than had been hitherto done. He then exhibited some prints taken by him soon after the process was made public, all of which, he said, remained as perfect in tone as when produced

After some further discussion, the meeting concluded.

Newcastle-upon-Tyne and North of England Photographic Society.

The regular monthly meeting was held on Friday night, 1st inst., in the Tower, New Bridge Street, Mr. G. C. Warren, one of the Vice-Presidents, in the chair.

As a part of the preliminary business, the Chairman read a list of new members who had been elected since the 21st December ult., and were as follows:—The Right Hon. Sir Frederick Pollock, Lord Chief Baron, and President of the London Photographic Society (patron); Right Hon. T. E. Headlam, M.P.; Sir David Brewster, Principal of the University of Edinburgh; the Rev. J. C. Bruce, A.M., LL.D.; the Rev. John Lockhart, A.M., D.D.; A. H. Wall, Esq.; F. Joubert, Esq.; Thomas Sutton, Esq., A.B.; T. Ross, Esq.; Dr. Hill Norris; G. Wharton Simpson, Esq.; George Shadbolt, Esq.; J. Dallmeyer, Esq.; Jas. Dewar, Esq.; Jos. Watson, Esq.; and David Zenner, Esq., analytical chemist.

An interesting paper was read by Mr. Thomas Davidson, optician, late of Edinburgh, on "The position Diaphragms should occupy in View Lenses." Mr. Davidson illustrated his paper by reference to diagrams, pointing out the correct position the diaphragm should occupy, and showed that the distance a diaphragm should be from the lens, to be thoroughly effective, should be regulated according to the size, aperture, and the focal length of the lens. The larger the diaphragm used, the nearer it should be placed to the lens; the smaller, the further from it. Some opticians, he stated, have their diaphragms to slide or turn round in front of the lens, and at equal distances from it, whatever the diameter of their aperture. The impropriety of this was pointed out by reference to the diagrams. It was also shown that, by attempts to secure flatness of field, distortion of the image was produced, particularly towards the margin of the picture, the parts there being enlarged disproportionately to the centre.

At the close of the lecture a conversation ensued, when

Mr. Warren introduced two views of the interior of Whitfield Church, and remarked that when first printed they were so much overdone as to appear quite useless; by immersing them in tolerably strong ammonia, they were considerably reduced in intensity, but had a very unfavourable appearance, being very flat and mealy looking. However, on toning them in the alkaline gold bath, to his great surprise, they became good vigorous impressions.

Mr. North laid upon the table three very beautiful photographs, two of them copies from old sepia drawings taken 150 years ago, one of the old Norman Keep, Newcastle-upon-Tyne, and the other the interior of its chapel; these he presented to the portfolio of the society.

A good display of large photographs and stereoscopic pictures, accompanied by stereoscopes, were placed on the table by the members.

Several fine transparent slides were shown by Mr. LAWS, and were much admired. Mr. Laws kindly promised, at a future meeting, to detail the method he employs for their production, and which, from what was gathered in conversation, appears to have some points of novelty about it.

Illuminated transparent slides were also shown by Messrs. Willis and Anderson.

Votes of thanks were given to the lecturer and chairman, also to Mr. North for his present.

The tannin and albumen process will be brought before the next meeting, on the first Friday in April.

Photographic Notes and Queries.

WAXED-PAPER PROCESSES.

SIR,—I would strongly recommend your correspondent 'Aer" to make himself familiar with the ordinary waxed paper process in its simplest form, before trying the turpentine method. I have obtained very good results using the formulæ given by Mr. Crookes in a little pamphlet published by Chapman and Hall, about four years ago, entitled "A Hand-Book to the Waxed Paper Process in Photography," by William Crookes. This process seems to me much the best for an amateur whose opportunities of practising the art in the field are few and far between. The turpentine waxed paper process is, I think, less convenient because the sensitizing, exposure, and development must be done the same day to make sure of good results, (this, at least, is my experience,) which, in many cases, turns what should be an exquisite pleasure into an arduous toil, whereas the ordinary waxed paper, when sensitized, will keep several days,—a great advantage. My general practice is, to sensitize one day, expose the next, and develop on the third; this is the safest plan as a general rule, but the paper, if well prepared, is quite good at the end of a week after sensitizing, and may be exposed at any time during this period Nothing more definite can be said about keeping, as so much depends on the washing after sensitizing, and the temperature of the weather. Time of exposure again is a point which does not admit of any rigid rule being laid down respecting it. With common waxed paper and a lens that I had not used before. I would allow six minutes for a building well lighted, and at least eight for a near view containing foliage. The two results compared, would be very instructive. It is well to bear in mind that *under* exposure is the fault most generally committed. There seems to be a sort of instinct in exposures for all processes; the operator *feels* that he is doing right, but is quite unable to explain why it is so. The greatest nuisance connected with the Waxed-Paper Process seems to me to be the badness of the Waxed-Paper sold at the shops, I have tried most of the best houses in London, and paid all prices, meeting with the same vexatious results of bad paper, and in answer to my complaints I am always told that there is so little demand for the article that it is not worth while to spend much pains on its preparation. Wax your own paper, say some—but where can you get pure wax? I should be much obliged if some correspondent would instruct me how to extract the wax from the comb, and render it available for photographic purposes.

Yours very truly, A WAXED-PAPER MAN.

TURPENTINE WAX PAPER PROCESS.

SIR,—Seeing a few enquiries *re* Turpentine Wax Paper in the last number of the NEWS, I would in reply, strongly advise him not to try the process without the second iodizer, on account of the length of exposure required; let him omit the eggs in the second solution, and use about double the quantity of iodide of potassium recommended in the work to which he refers.

1. It seems to give better negatives.
2. Two years *or more*.
3. From ten to fifteen minutes, a picture exposed a few minutes more or less makes little difference except in the development.
4. Decolourize with a weak solution of salt water (say half-an-ounce of a 4-grain solution to 12 ounces of bath).
5. If kept between blotting-paper so as to exclude air 14 days.
6. English paper won't do, use Saxe.

"Aer" will find no difficulty in working the process out, *provided* he keeps the developing dishes, &c., thoroughly clean.

Yours truly, T. W. P.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 6*th March*, 1861.

A new process of engraving, termed *Chrisotipy*, has been invented by M. Firmin Didot, the object of which is to transform a plate engraved in the ordinary manner (*en creux*) into a relief, in which the subject can be printed on the usual printing-press, or, as it is usually termed, surface-printed. The process is as follows:—On a steel or copper-plate, covered with the usual engraver's varnish, the subject is engraved with the burin in the usual manner; when finished it is placed in a bath of acidulated water, composed of water five-tenths, nitric acid four-tenths, and sulphuric acid one-tenth—to which a small quantity of sal ammoniac is added. When the plate is sufficiently bitten-in it is removed from the bath. The depth of the lines should be uniform, and the covering of such portions of the design as are required to be more or less dark with varnish, as in mezzotints, should be avoided.

This first biting-in terminated, the varnish is removed from the surface of the plate, then a coating of gold is applied all over it, on the engraved side, either by the electrotype or by other process of gilding.

When gilt, the lines of the engraving are filled with a varnish which is not attacked by acids: this varnish is composed of wax, resin, and engravers' ordinary varnish, and must be applied over the entire surface of the plate, by heating the latter so as to cause the varnish to melt. After removing with a scraper all the varnish from the surface of the plate so that none remains except in the lines of the engraving, those parts of the surface which are covered with gold, must be rubbed with pumice and charcoal, leaving the lines intact, so that after this operation is completed no gold remains on the surface of the plate, except in the incised lines protected by the varnish, the other portions of the plate being now denuded.

The plate is again placed in a bath of water acidulated with nitric acid, with the view of biting those portions of the plate which are now unprotected with varnish or gold; it results that at the end of a certain time, the lines which were sunk below the surface of the plate become in relief, and that the parts which were in relief, on the contrary, are now *en creux*. The second action of the acid bath must be three times as long as that of the first, the lines originally sunk in the plate will then have a relief twice as great as their original depth. On removing the plate from the bath, it is warmed and the varnish rubbed off

White wax dissolved in benzine presents a useful coating for implements or tools of iron and steel, to preserve them from rust. At ordinary temperatures 1 part of wax dissolves in 15 parts of benzine: the solution is applied with a soft brush, and the benzine quickly evaporating, leaves an extremely thin but uniform coating of wax, which effectually protects the metal even from acid vapours. It also possesses a superiority over other varnishes in being elastic and in not cracking.

If a varnish free from tackiness could be obtained from caoutchouc, it might prove useful either alone, or mixed with resins in protography. When dissolved at ordinary temperatures, in benzine, the mixture being frequently shaken, the gelatinous caoutchouc i for the most part dissolved. The solution is not so fluid as benzine, but upon leaving it to repose for a time a perfectly limpid solution may be obtained. The insoluble flocculent deposit may be separated by passing the solution through fine linen under pressure. This solution will mix with oil or spirit varnishes. If properly dried it possesses no gloss, if unmixed with resinous varnish. As it is quite colourless it is well adapted to the varnishing of maps, engravings, &c.

Talk in the Studio.

The Photographic Exhibition.—The Exhibition will close about the end of the present month. The attendance has been, we believe, unusually good.

The Panoramic Lens.—Mr. Ross is, we understand, progressing with the manufacture of panoramic lenses with every prospect of success. Two or three first class photographers we understand have ordered them The manipulatory difficulties in working curved glasses are much less than might be expected. A few days ago, in the laboratory at King's College, we saw Mr. Sutton coat, with collodion, several curved plates, 16in. by 6in., as easily as flat glasses, and without spilling a drop or forming a ridge. We anticipate that fine results will be produced during the coming summer.

Garibaldi's Son.—A contemporary publishes the following: Mr. Stortz, photographic artist, Liverpool, has just received the following characteristic note from the regenerator of Italy. Garibaldi has a son being educated near Liverpool, and Mr. Stortz forwarded to the parent a beautifully-executed portrait of his boy, finished in water-colours :—Mr. Stortz, Liverpool,—I am extremely grateful to you, kind sir, for the agreeable present made to me of the portrait, in water-colour, of my Ricciotti. Thus we have now in our family an absentee whom we love. Command, pray, yours, &c., G. Garibaldi.

Caprera, Feb. 4th, 1861.

The Electric Light.—A company is, we understand, forming for the purpose of bringing Professor Way's Mercurial light to a successful commercial issue. Photographers will probably find the light brought more readily within their means when the company have made their arrangements.

Visiting Card Portraits.—We gave, on page 13 of the present volume, in the number for January 11th, a process of intensifying for producing negatives of peculiar delicacy, especially suitable for visiting card portraits, as used by Mr. Lacy of Ryde. We have recently had an opportunity of inspecting a large number of specimens produced by this process, which certainly equals, and in some respects surpasses, all similar portraits we have seen. In a recent conversation with Mr. Lacy he called our attention to a point we omitted to state, and which he regards as of considerable importance; namely, that the negative is dried before intensifying. Some large specimens we have before us show that the process is not less successful on large plates than on small ones.

Turner's "Liber Studiorum."—From an advertisement in another column, it will be seen that the Science and Art Department at South Kensington are about to produce negatives of the original drawings in Turner's "Liber Studiorum." It will be seen that in regard to the printing and publishing the Department are, in this instance, desirous of enlisting the aid of private enterprise.

Photography as a Civilizer.—No expedition of a civilizing tendency is now considered complete without the aid of photography. A portion of the outfit intended for a second Oxford Mission to Africa, was exhibited at the photographic meeting on Tuesday evening by Messrs. Murray and Heath.

Modified Fothergill Process.—Mr. Gabb, one of our correspondents, sends us the following modification of the Fothergill process. As might be anticipated, the plates do not keep well, but are sensitive, and give good vigorous negatives, as is shown by the print forwarded to us. After having sensitized a plate, pour over it the preservative solution completely, holding the plate upon a pneumatic holder. I have generally poured it over twice to ensure the covering of the whole surface—then wash the plate *thoroughly* with a free supply of common water, and set it by to dry, either spontaneously, or by the aid of artificial heat—the latter perhaps the best. The preservative solution consists of—

Sugar of milk	80 grains
Distilled water	9 ounces
The white of	1 egg

The sugar of milk dissolved in this water, the albumen then added and well shaken up with it. I think the plate is most sensitive if this solution has been mixed a few days before use. I first of all tried sugar of milk alone. I have since seen that sugar of milk and alcohol have been used by a gentleman in Italy with success. I have not tried it with alcohol—but with the albumen in the proportion above mentioned the plate is very sensitive and manageable. The development is with pyrogallic acid and silver in the usual way.

To Correspondents.

Susanna.—Marine glue is the best cement for glass. You will obtain suitable paper of any respectable dealer, but we cannot mention names.

J. P.—We suspect a little gold has, by some means, found its way into your bath. Your best plan now will be to render the bath alkaline by oxide of silver, and then placed in sunlight for a while. Then filter, and if necessary add a minute portion of nitric acid. This method often cures a bath into which some unknown foreign matter has found its way.

Stereo-Cam.—The front lens of a portrait lens, properly stopped down, will often give very good landscape results; but not always so good as a lens made expressly for the work. 2. A twin-lens camera by all means: a single lens for stereoscopic purposes has numerous disadvantages, as you cannot take moving figures; and when the pictures are not taken simultaneously, they frequently have different effects of light and shadow. 3. The maker you mark H we think decidedly the best, as well as a little lower in price. The new stereo lens you refer to, is, so far as our experience goes, the best lens in existence for the purpose. Rack and pinion adjustment is not necessary; indeed in twin-lens cameras it is troublesome. It is better to focus from the back. A certain amount of decomposition has probably taken place in your plain collodion. Add from half a grain to a grain of a bromide to each ounce when you iodize it.

Tit Tat To.—The collodion you mention is, we believe, iodized with cadmium; and, as in evaporating it, you lose the ether first, you will probably very soon get it into gelatinous unmanageable condition. The best means of obtaining more body is to add a grain or two more soluble cotton to each ounce. Evaporating will not injure the sensitiveness. You will find it a good plan to mix a little of some collodion having more of the organic element. You may intensify a negative after fixing by pouring a portion of a five or ten grain solution of silver over it, and then develope again with pyrogallic acid. It is important, however, that the negative possess sufficient detail, or hardness will be the result. You will find an excellent intensifying process in the Photographic News Almanac for this year. 3. The objection to the old hypo-toning bath to which you refer, does not arise from any difficulty in getting good tones, but from the want of permanency in the results. It is not necessary to change the bath, but take care to keep it quite free from acidity; and it is well to finish with a few minutes in fresh bath of new hypo, saturated solution. You had better try the alkaline gold bath, if you desire permanency.

W. L.—The aceto-nitrate bath, used for the albumen plates, will occasionally require decolourizing. Citric acid, as recently described by Mr. Tunny, will be bettter for the purpose than kaolin. Liver of sulphur can be had of all respectable photographic chemists. It is not a pleasant-smelling article.

W. A. S.—With a bright light and sensitive plate instantaneous pictures may be taken with landscape lens; but a suitable double combination is better. 2. There is no objection whatever to white for outside of developing boxes, &c.; but, in hot weather, a positive advantage. It is not necessary to be a member of any photographic society to be enabled to send pictures to the Exhibition.

R. N.—We think that photography may be made very valuable in connection with hydrography, and shall be glad if we can aid you in its application. The use of bromized collodion and iron development, together with a good lens will enable you to photograph headlands, &c., from the deck of a ship under weigh, provided the light be good. 2. You will find an articles on Instantaneous Photography in the Photographic News Almanac for this year, and inseveral numbers of the News. 3. You will, we think, be able to get the bellows portion of a camera from a respectable camera maker. See our advertising columns. 4. The market for photographs would depend as much on the picturesque nature of the scenery and the excellence of the picture, as upon the scene being remote and little known; but we should imagine that Africa and South America, would furnish subjects full of beauty and interest, and if well executed and of a large size would sell. It is probable that good pictures of some of the largest ships would sell. For these probably stereoscopic pictures would be desirable. We are generally at the office on Thursday afternoons, but uncertain at other times. We shall be happy to see you if you can call.

A. H. S.—There does not seem to be anything amiss with your waxed paper. You do not state exactly what your difficulty is. Remember that especial cleanliness is necessary, especially in regard to the dishes. We see no reason why you should not succeed with the resin process; but you will ascertain best by trying.

Seaside.—We answered your question a few weeks ago. The Exhibition closes at the end of the month.

Wm. Bartholomew.—You need not anticipate any bad effects from your method of preserving the gold bath. Your print speaks well for the tannin process. You will get softer results by using a bromized collodion.

Alpha.—It is necessary to be proposed by a member. We will have pleasure in proposing you. The subscription is half-a-guinea yearly.

G. P.—The subject of our correspondent's letter is interesting; but there are two reasons why it cannot be published as it stands. It deals somewhat captiously with the labours of a gentleman who exerts himself very disinterestedly for the public good; and it is anonymous. In a discussion between two persons they should stand on equal terms, which is not the case when one avows himself, and the other preserves himself incognito. We will refer to the subject of the letter in our next.

O. X. X.—You have succeeded well in mounting your lens; there appears no fault with it. Your best plan with your bath will be to follow the instructions given to J. P.

Hy. Cooper.—We are not aware that the details of the especial albumen process used by Messrs. Soulier and Ferrier have been published; but you will find a very simple and efficient method of using albumen for the same purpose in the Photographic News, No. 129, also several articles on the subject in Vol. IV.

C. K.—The raisin extract referred to by Mr. Davis is made by boiling raisins in water. You will find particulars on p. 351 of our 4th vol., or p. 70 of our Almanac. The negatives are very fine: but as yet we cannot say how long they will keep. You may prepare the plates at home by candle light with advantage. Do not work too near the light of the candle; and be careful with the vapour of the ether.

H. S., Phos., N. W., O. X. X., F. Lane, and several other Correspondents next week.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 132.—March 15, 1861.

THE TANNIN PROCESS.

One of the chief features of the new edition of Mr. Hardwich's "Manual," is a new dry process, or modification, the discovery or first application of which is due to Major Russell. The preservative used in this process is a solution of Tannin, which leaves on drying a varnish-like film, not peculiarly hygrometric, or sticky to the touch, but readily softening with water, and affording facilities for quick and easy development. The chief advantages claimed for the process are simplicity of preparation and certainty of result, clean, sharp, vigorous negatives of remarkably good tone being generally obtained.

Mr. Hardwich speaks very highly of the process, and regards it as "most closely allied to wet collodion, both as regards the composition of the sensitive film, and the quality of the picture." Of the operation of the preservative he says:—

"When applied to the surface of the excited film, the tannin keeps open the pores of the collodion, as before described, and the mechanical condition of the film appears to be intermediate between that of Norris's and Fothergill's, being slightly more permeable than the latter, but considerably less so than the former. Independently of this, however, tannin has a very remarkable effect in *stimulating* the sensitive iodide, and causing it to take a much deeper and more decided impression in the camera.

"It would not be correct to speak of this acceleration as an increased sensitiveness imparted to the iodide, but rather as an augmentation in the force of development, in consequence of which the image starts out quickly, and with more contrast between the extreme tints; the colour of the image is also different, the particles which compose it being no longer grey and crystalline, but finely divided and opaque, so that the negative possesses all those qualities which the photographer requires,"

Mr. Sutton, who has experimented largely with the process, says he has "very little doubt that the tannin preservative will turn out the right thing, and that this process will quickly supersede wet collodion for all out-of-door purposes, in which rapidity of action is not required." We have been present at many of Mr. Sutton's experiments at King's College, and have seen many very fine results obtained; but from the drawbacks we have there seen, and those occurring in our own hands, we are scarcely so certain of the universal success of the process.

The details of the manipulations are as follows:—The plate is coated with collodion and excited in the usual bath, on removal from which it is thoroughly washed with common water from a tap or jug, to remove as much as possible of the free nitrate of silver; and a final rinse with distilled water is recommended. A solution of tannin, fifteen grains to an ounce of water, is then poured upon the plate. The tannin may be had of any chemist, and is very soluble in water: the solution should be filtered before use. It is recommended to pour on sufficient of the solution to cover the plate, and, throwing that off, coat again, and place the plate to drain whilst another plate is being prepared. After draining awhile, the plates are to be dried by means of artificial heat.

Mr. Hardwich recommends, as a simple drying box, the placing of a heated flat iron on a levelling stand in common deal box, around the sides of which the plates can be arranged and dried in a few minutes: in our own experiments we used the flame of a spirit lamp for drying the plates. The exposure is six or eight times as long as that required for wet collodion plates under similar circumstances. On proceeding to develope, the plate is first moistened with common or distilled water—which is very easily effected, as the film is not repellant of water—and then developed with pyrogallic acid and silver. The strength of the developer may vary with circumstances, but about two grains of pyrogallic acid to an ounce of water is a good strength. To this is added a few drops of a twenty-grain solution of nitrate of silver or citro-nitrate of silver, according to the tone desired. If very black tones are desired, with a slightly purple tone by transmitted light, the latter should be used, one grain of citric acid to each grain of nitrate of silver in the solution should be added. If red tones are desired, acetic acid should be added to the developer in the usual way, about fifteen minims to each ounce of developing solution. The development is not so slow as in most of the dry processes, from three to five minutes sufficing when the plate has been properly exposed.

The collodion should be of the kind usually recommended for the dry processes, giving a powdery, porous film, not contractile, and repellant of water, and we think that alcohol at least in equal proportions to ether should be used in preparing the collodion. Some of the best results we have seen produced by this process have been from plates coated with alcoholic collodion prepared by Mr. Sutton. Either a simple iodide, or an iodide and bromide may be used; but we decidedly recommend the latter, inasmuch, as the tendency of the tannin is to give excessive vigour, and without the use of a bromide this tendency is apt to produce hardness. The collodion we have used for the purpose, and which seemed to possess the right qualities, was made by the formula we have given in our Almanac, which we will here briefly recapitulate:—Pyroxyline of a powdery character and very soluble, five or six grains in each ounce of solvents, consisting of one part ether, sp. gr. 725, one part alcohol, sp. gr. 805, and one part alcohol, sp. gr. 820. To each ounce of normal collodion two grains of iodide of cadmium, two grains and a half of iodide of potassium, and about half a grain of bromide of cadmium. This collodion had been made nearly twelve months, and was as sensitive in the wet process as when first made.

The results, as we have said, are very fine, the negatives being very brilliant and vigorous, and remarkably clear in the shadows, any foggy deposit on which may be rubbed off when dry without injury to the negative. There are, however, two serious drawbacks, which will, we think, materially tend to prevent the general adoption of this process. The first is one common to all processes more or less, if great care and cleanliness be not used, but we think belongs to this process in a pre-eminent degree, at least, so far as our own experiments, and opportunities of observing those of others give us an opportunity of judging: we are referring to liability to stains, this increased liability apparently arising from the fact that tannin is in itself, in some degree, a reducing agent. The necessity of careful and cleanly manipulation, however, would not be an objection in the hands of the clever photographer, if results comensurate with the efforts were obtained.

A more fatal objection exists, however, in the tendency which the film has to leave the plate in the processes of developing, fixing, and washing. This is a defect common, in some slight degree, to many of the dry processes, but in this it seems to exist in a pre-eminent degree, and seems to be the result of some action of the tannin. We arrive at this conclusion from the fact that in some experiments on relative sensitiveness, we simply washed and dried some plates coated with the same collodion as was used for the the tannin plates, and these showed no such tendency in the subsequent washing processes as was manifested by the tannin plates. A collodion adhering with very great tenacity to the glass will doubtless to some extent prove a remedy; but whether the tendency can be entirely obviated remains to be ascertained. Mr. Hardwich has recommended as a remedy—and insists on its importance in large plates—the coating of the glass with a two-grain solution of gelatine, and letting it dry prior to coating with collodion. This would, undoubtedly, largely remedy the difficulty; but it would at the same time materially destroy the especial quality which recommends the process—the simplicity of preparation—whilst it would introduce an element of injury to the exciting bath; so that we apprehend if this gelatine coating be absolutely necessary, few will be tempted to give up dry processes which they have worked successfully, for the use of tannin.

On the score of sensitiveness no especial claims are made for this process. Mr. Sutton states, as the results of his experience, that the exposure required for tannin plates is about six times that required for wet collodion. Mr. Hughes informs us that he found that a tannin plate required seven minutes, and wet collodion one minute, to produce similar negatives with the same lens, light, &c. We have not tested a plate with wet collodion at the same time, but our experiments corroborate these ideas as to the exposure required. Mr. Sutton gives about three minutes as the exposure necessary with a view lens of five inches focus, quarter-inch stop, and a good light. We tried some plates with a Dallmeyer's new stereo lens of four inches and a half equivalent focus and three-eighths stop, and gave a minute and a half exposure. We also tried some plates prepared with the same collodion at the same time, and simply washed and dried without any preservative coating at all, and gave them a similar exposure. The latter, on development, appeared, sufficiently exposed, but thin and weak in the lights, and had a foggy deposit on the shadows. The tannin plates, on development, appeared slightly under-exposed, but were red and vigorous in the lights, and clear and transparent in the shadows. The light was pretty good; but there was no sunshine. If the plates are over-exposed the image is visible when the plate leaves the camera.

The keeping properties yet require testing, but where any long-keeping qualities are desired, it will be desirable to use a dilute salt solution—five grains of common salt to an ounce of water—as recommended by Mr. Hardwich, after washing the plate and before applying the tannin. As all traces of free nitrate of silver will be removed by this operation it will be desirable in all such cases to use a bromo-iodized collodion.

There is one especial use of these plates which we have not mentioned; they are especially suitable for the production of transparencies, printing by superposition of the negative. The rich black tone produced, the sharpness and crispness of detail, and the clearness in the transparent lights of the picture, have much the effect of transparencies on dry albumen plates. About four seconds exposure in the printing frame, to diffused daylight in a room, is sufficient exposure to produce capital results.

Those of our readers interested in the preparation of dry plates will doubtless give this process a fair trial, and we shall be glad to learn the results of their experience to afford opportunity for comparison. So far as we can see at present we are not sure that it promises less trouble in preparation, or better results than the process recently proposed by Mr. Sebastian Davis in our columns, which we will briefly recapitulate: coat the plate with a powdery collodion, containing, in addition to iodides of potassium and cadmium, a small portion of bromide and of chloride of ammonium. Sensitize in the usual way, and on removing the plate from the bath immerse in salt and water, and give a final rinse with distilled water. Then coat with a mixture of albumen and sugar syrup, or raisin extract, in equal parts, to which a few drops of ammonia have been added; after about a minute wash and dry. These plates have a medium degree of sensitiveness, keep well, develope with clean, rich, and vigorous tones, and have no tendency to self dstruction by the film leaving the plate. This appears to be about as certain and simple a modification of the Fothergill process as we have seen.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Background.—A term sometimes used to indicate the sky and distance of a landscape, but more frequently applied to the space which lies behind a picture's principal object, or objects. How often is the threadbare anecdote to be repeated, of the great painter, who told the would-be pupil that if he could paint his backgrounds he could paint his pictures? No one denies the vital importance of a good background, and yet how few ever treat it in any other than a mechanical and conventional method. As to the photographer, his sole aim seems to be that it should be free from spots, stains, and comets, and relieve dark hair with light, and light with dark. A few of the simpler principles which should regulate the choice and management of backrounds may be useful. If you illuminate a sitter—I now refer to portraiture—with a weak light, to secure a powerful effect of light and shade, the lightest portion of the background must be dark enough to give value to the lights of the face, and the darkest portions should not be so dark as to weaken the intensity of the darker shadows, nor so light as to give them a spotty or patchy effect, by rendering them unduly prominent as the darkest parts of the composition. If, on the contrary, you illuminated with a strong diffused light, and obtained a very delicate effect with tender shadows, having powerful reflected lights, a dark heavy background would kill all the beauty and modelling thus obtained, and render the face a mere flat patch of light. Again, a dry, hard effect will arise from having a background which relieves with equal force every part of the figure. An inlaid appearance destructive of relief will arise from a background which exhibits one uniform appearance of texture, and a monotonous evenness of tone and colour; an unpleasant effect will also arise if the darkest or heaviest portion of a background be at its top instead of its base, unless the latter be nearly allied to it in tone, &c. The background should serve, in short, to give force, roundness, and brilliancy to the principal portions of your subject, by the judicious contrast of tones and intensity. White backgrounds, or, in other words, *no* backgrounds exhibit very bad taste. The high lights want brilliancy, because they are no longer the most luminous parts of the picture, huge masses of the same intensity or whiteness killing their force, and effect; the half tints acquire an undue amount of force and so lose softness and delicacy, and the shadows lose transparency. These remarks apply also to those terrible abominations "white skies," or, rather, *no* skies, in which case not only do the lights lose their luminous character, the half tints their delicacy, and shadows transparency, but aerial perspective is quite destroyed, and a flat map-like character substituted for that of space and relief. See *Adhesion.* By the proper placing of a model against the darker or lighter portions of the background, the more beautiful outlines may be rendered prominent, and monotonous, angular, or otherwise objectionable portions lost in a mass of dark. Breadth of effect may be secured by properly managing the lights and darks of the background, indeed when the portrait is a mere bust—or what painters sometimes jocularly call, a cod's head and shoulders—this is frequently the only method of securing breadth of chiaroscuro. Do not get a very dark background to contrast a white dress, as this would render the latter flat and intensely conspicuous; nor for the same reason place very dark drapery against a very light background. A swarthy model in dark drapery must not have a too light, nor a fair delicate complexioned model in light drapery a too dark, background. If you make use of a painted cloth to represent an interior or out-door view, the horizontal line must be at somewhere about the height which your lens is most generally placed at, and the vanishing point nearly opposite the spot occupied by the camera. The lights should be far removed from white. The best plan is to prepare it of a drab ground, and lay it in with different tones of the same or a similar colour, leaving the ground to represent the high lights. Then every part will retire, and the figure before it be in proper relief. If this background be painted in distemper, or colours prepared with size, take care not to use the glue or size in excess, as the colours will then crack and peel off.* A background of this description should be sketchy, faint, and slightly executed. If too forcibly painted, it will destroy the general effect. I have just said that the horizon of a landscape background and the vanishing point should be opposite the lens, I may perhaps for the sake of such operators as are not acquainted with perspective explain why. The figure and the background are supposed to be taken at one and the same time, and the camera has the place of the spectator by whom they are taken. Now suppose we have a real figure before a real landscape, if I look up at a figure I obtain one view of it, but if I look down on it I get another and quite a different view, and the horizon of the natural landscape behind the figure is always exactly the height of my eye. To prove this you may sit down before a window and mark on the glass the height of the horizon, then rise and as you do so you will find the horizon also rises and is again exactly opposite your eye. A picture then in which the horizontal line of the background represents the spectator as looking up at the figure from a position near the base line, while the figure itself indicates that the same spectator is at that identical time standing with his eyes on a level with the figure's breast or chin. Such productions are evidently false to art and untrue to nature. It is hardly necessary perhaps to add that the light which illuminates the sitter should not be in opposition to that by which the landscape is lighted.† A figure which receives a strong direct light from some one comparatively small aperture, giving it the dark and powerful shadows of in-doors, should should not be placed in the full broad light of the open air in which the shadows are weak and the lights diffused. In painting such a background too it is well to concentrate the lighter portions near the centre of the screen: to keep the lights down and to avoid strong shadows; to prevent lines from cutting the space into sections, and the space about the position of the sitter's head clear and free. White and black in contrast are fatal to the proper character of a background, for, as Fresnoy tells us—

> "White, when it shines with unstained lustre clear,
> May bear an object back or bring it near;
> *Aided by black it to the front aspires,*
> That aid withdrawn it distantly retires."

White, however, should be kept entirely out of your background, in order that the high lights of your subject may be luminous and brilliant, as I have before said, for, to quote Fresnoy again—

> "Give then each foremost part a touch so bright,
> That o'er the rest its domineering light
> May much prevail."

The general fault in the painted screens we see behind photographs arises from introducing too many objects. Simplicity and breadth should always be their main characteristics.

Back-painting.—A name given to a method once common with cheap print-sellers of painting mezzotints with varnish colours applied at the back. A good many photographs were once spoiled in the same way; and it is said that some rash individual actually took out a patent for the childish process.

Balustrades.—Frequently used as accessories in photographs, and very useful in posing; but they should be so painted in distemper or turpentine as to prevent glossiness of surface, and not to appear too prominent or light in the photograph. By using silver sand in the flatting, or turpentine colour, an effect closely resembliug that of stoue may be got.

* Four ounces of glue to nearly a gallon of water is about the usual proportion.

† I need only point out the frequency with which this bit of common sense is violated, in the carte de visite portraits, to justify this morsel of advice.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Having given in our last an account of the best method of preparing iodide of potassium, we proceed now to notice the various impurities and adulterations to which it is liable. The commercial salt may contain carbonate of potash, iodate of potash, chloride of potassium or sodium, sulphate of potash, sulphide of potassium, and organic matter containing sulphur. The *carbonate of potash* gives rise to an alkaline reaction in the solution of iodide of potassium, a greater tendency to deliquesce, and occasions an effervescence on the addition of acids. It may be removed by neutralising the alkaline solution with a little hydriodic acid, or by powdering the salt and boiling it for some time in strong alcohol. The carbonate will be left behind whilst the iodide is dissolved. In either case, by filtering and crystalliziug the iodide may be obtained free from carbonate. The presence of *iodate of potash* may be detected dy dissolving in water and adding a few drops of hydrochloric or tartaric acid. If iodate be present the solution will turn brown from the separation of iodine. It may be purified from this by careful drying and then heating to dull redness. After cooling and crystallizing from water the iodide will be found free from iodate. *Chloride of potassium or sodium* may be detected by adding nitrate of silver in slight excess to the aqueous solution, then pouring a little solution of ammonia over the washed precipitate, and testing the filtered liquid with pure nitric acid; if a white precipitate be thrown down it will show that a chloride is present. *Sulphate of potash.*—This impurity may be easily detected by dissolving in water and adding a drop of chloride of barium with some hydrochloric acid. A white precipitate which remaius undissolved in the acid will show the presence of a sulphate. This can be removed by dissolving in alcohol and crystallizing as above directed, the sulphate being quite insoluble in that medium. *Sulphide of potassium* may be detected by adding a few drops of sulphuric acid to the aqueous solution, if sulphide be present the disagreeable odour of sulphuretted hydrogen (rotten eggs) will be perceived. If the presence of *organic matter containing sulphur*, probably xanthonate of potash, be suspected, the iodide of potassium will have a nauseous taste like assafœtida, and will turn greyish brown, with evolution of sulphurous acid, when heated. The residue, treated with water, will leave charcoal containing sulphur, and sulphate of potash will be found in the solution along with the iodide. This impurity occurs when alcohol, together with sulphuretted hydrogen or a metallic sulphide is used in the preparation. A salt containing this impurity or the previous one of sulphide of potassium should be at once rejected, as it would be totally unfit for photographic purposes, and it would not be worth the amateur's while to attempt its purification.

Iodide of potassium is sometimes intentionally adulterated with other substances. The following is a very convenient test for its purity in this respect:—One atom (165·2 parts) of iodide of potassium completely precipitates one atom (136·8 parts) of chloride of mercury from an aqueous solution; but the insoluble iodide of mercury again dissolves completely in one atom of iodide of potassium. Two atoms, or 330·4 grains of the iodide of potassium to be tested, and one atom, or 136·8 grains of pure corrosive sublimate are each to be dissolved in six ounces of water. To two ounces, accurately measured, of the solution of iodide of potassium, the solution of corrosive sublimate is then to be added very gradually until a permanent precipitate begins to appear; if two ounces of the latter solution are required for this purpose the iodide of potassium is quite pure; but if a permanent precipitate remains when only one ounce of the corrosive sublimate solution has been added, the iodide of potassium is adulterated one-half with foreign substances; and if one ounce and three-quarters of the corrosive sublimate are required to produce a permanent precipitate, it will show that seven-eighths of the salt is iodide of potassium, and the other eighth is made up of adulteration.

Pure iodide of potassium has the following properties:—It should dissolve entirely at ordinary temperatures in three-quarters of its weight of water, and in six times its weight of strong alcohol. It separates from its aqueous solution in white crystals, sometimes semi-opaque, and having forms derived from the cube. The crystals melt below a red heat, have a sharp taste, and when dissolved in water turn reddened litmus paper blue. They are not deliquescent except in very moist air. The commercial salt frequently deliquesces owing to the presence of carbonate of potash.

Iodide of ammonium.—This salt may be easily prepared by adding to the solution of proto-iodide of iron prepared as recommended in our last chapter, a solution of carbonate of ammonia, until the liquid after stirring, continues to smell slightly of ammonia. It must then be heated and filtered. The solution on evaporation yields crystals of iodide of ammonium. If the carbonate of ammonia were pure and the iodide of iron prepared with good materials, the iodide of ammonium will be pure, otherwise it will require crystallizing again. It forms small colourless crystals, which are very unstable and apt to turn brown owing to the separation of iodine. The salt is more soluble both in water alcohol and ether, than the potassium salt. Its solution likewise turns reddened litmus paper blue. When colourless, it may easily be kept so by being put away in a dry state away from the light. And if it be brown it may be decolourised by placing it in a small flask and pouring over it a little ether. On shaking, the iodine will be dissolved out and the white salt left behind. The commercial iodide of ammonium frequently contains sulphate of ammonia and carbonate of ammonia. The latter being added to preserve it from changing colour. The best way to detect the presence of these is to dissolve a little of the salt in water, and then to add a clear solution of chloride of barium. If a white precipitate be produced it shows that a sulphate or carbonate is present. Now add a couple of drops of dilute hydrochloric acid, and if the precipitate dissolves with effervescence it shows that carbonate of ammonia was present, while if the precipitate still remains undissolved it indicates the presence of a sulphate. From the latter it may be purified by dissolving in hot alcohol, filtering, and allowing to crystallize; the sulphate being insoluble in alcohol will be left behind on the filtering paper. From carbonate of ammonia the iodide may be freed by dissolving in water and evaporating to dryness on a water bath. The carbonate being very volatile will entirely go off.

Iodide of cadmium is another important photographic iodide, and one which is very easy of preparation. Take some pure metallic cadmium and cut or rasp it up into a coarse powder: then take pure iodine in about twice the quantity of the cadmium. Place them in a glass flask together, and cover them slightly with alcohol. The two elements will combine with heat and the colour of the iodine will soon disappear. When that is the case add water until the crystalline compound which results from the union of the cadmium and iodine has dissolved, and filter from the few grains of the metal which will be left behind. Evaporate the solution over a water bath, and allow the salt to crystallize out. It may be rendered absolutely pure by a second crystallization from alcohol.

Iodide of cadmium so prepared forms large white tabular crystals of a pearly lustre, which do not deliquesce. They are very soluble both in water and alcohol. The only impurities likely to be present are those originally in the cadmium. Of these zinc is the most frequent; its presence prevents the crystals of iodide of cadmium from forming in a perfect manner, and occasions the liberation of iodine when dissolved in collodion.

WOODWARD'S SOLAR CAMERA.

M. Leon Foucault, well known to the scientific world by his ingenious method of demonstrating the diurnal rotation of the earth, has remarked that the discussion between Messrs. Claudet, Bertsch, Moigno, Thouret and others, on the solar camera, rests entirely, like most disputes, upon a confusion of terms. M. Foucault has endeavoured to elicit the source of the confusion. He shows that in Woodward's solar camera the little image thrown on the enlarging lens has never been regarded, as M. Thouret supposes, as an image of the negative to be enlarged; it is a real solar image, formed by the union of all the rays collected by the condensing lens. This condition being satisfied, it is right to maintain that the enlarging lens acts as if it had been contracted by a diaphragm to the diameter of the solar image.

Let, for example, C represent the condensing lens, L the enlarging lens, and E a screen placed at a distance corresponding to the conjugate focus of the plane N, where the negative must be placed. In an apparatus thus arranged, and in the absence of a negative, it is evident that the whole of the light spread over the screen is composed of the same rays which, in the plane of the enlarging lens, group themselves together to form a solar image. This image, therefore, contains in its small area all the light which, further on, is distributed over the surface of the screen. From this it follows that without changing the effect, or suppressing a single ray, we can, by a diaphragm, mask all the zone of the enlarging lens which exceeds the solar image.

If we now proceed to place a negative in the plane N, the glass which supports it having strictly parallel surfaces, the general direction of the rays will not be altered, the solar image will continue to be formed on the enlarging lens; only most of the rays in passing through the various points of the negative will undergo a partial and varying extinction, the effects of which will be repeated on the corresponding points of the image on the screen. In this manner an enlarged image of the negative is formed, solely in consequence of the partial and local extinctions it determines, without at all modifying the geometrical path of the persistent rays.

It is, therefore, reasonable to maintain that in the formation of the enlarged image, the region of the objective lens occupied by the solar image intervenes in an efficacious manner only, that the exterior zone gives passage to an insignificant proportion of the diffused rays, and that, consequently, it cannot impart, through spherical aberration, a faulty direction to the useful rays.

Is this equivalent to saying, that to obtain the best results it is indispensable to receive the focus of the condenser upon the enlarging lens? This is quite a different question. The sole result of the preceding explanation is, that everywhere where the bundle of illuminating rays constitutes an image of the luminous source, we may consider it as passing through a diaphragm of the same form and size as the image. By this simple consideration we easily arrive at foreseeing the part reserved to the various parts of the enlarging lens, whether the solar image be formed on the plane, or before or behind the optical centre.

In making the focus of solar rays fall upon the enlarging lens, it results that only one and the same portion of this lens is affected in the formation of the entire image of the negative, which, generally, is not a favourable condition to equality of effect. On the pretext of avoiding spherical aberration we fall into a graver inconvenience, which consists in a diminution of the field of sharpness. In this consists an inherent defect in the arrangement claimed by Mr. Woodward, and which cannot be considered as a complete solution of the problem of optical enlarging.

It would be preferable, in my opinion. M. Foucault observes, to make the solar image I fall beyond the enlarging lens L, on condition of giving to the latter the form of a meniscus, the concavity of which is turned towards the solar focus. We should thus have a system which operates in an inverse direction to the old camera of Wollaston, adopted by Daguerre.

This arrangement has given good results with a simple lens; but further resources may be found in the use of combination lenses.

AN APPEAL FOR THE PRACTICAL IN ARTISTIC PHOTOGRAPHY.

BY A. H. WALL.*

Gentlemen,—It is with no small pleasure that I respond to the invitation extended to me through the editor of The Photographic News, by placing in your hands the following unpretending paper:—A new branch of art has arisen, to the improvement and advancement of which, this, and kindred associations have been generously devoted. Its numerous applications and their varied character, have procured it admirers, professors, and practitioners among individuals of the most diverse characters, inclinations, sympathies and pursuits. It ministers to the pettiest sentiments of the meanest nature; and it soars above the aspiring ambition of the loftiest; now depicting the simpering expression of personal vanity; now bringing through the measureless abysses of space those mysterious images of other worlds, rolling in silent majesty upon their God-appointed ways. Filling the awe-struck soul of the mightiest astronomer with new thoughts and fresh conclusions, as he compares their invaluable records with those written by the Divine hand high in the mighty dome of the hushed and solemn night; and delighting the illiterate serving-man or maid with a sooty and distorted image of vulgar finery and commonplace features, in a six-penny glass positive, "with frame and glass, with a ring to hang it up by," all included. The mere "man of facts," as he delights to call himself. travelling in his little circle of ideas, with imaginative faculties and poetical sentiments locked up in darkness, and guarded by the stern hard jailor of common-place utility, and selfish advantageousness, patronizes photography; for, says he, "it is uncompromisingly true; it takes my portrait and it gives me the wort on the cheek and the squint in the eye; exactly as I am. It produces me a landscape, and I can count the leaves on the trees, the bricks in the walls, and the tiles on the roofs." Again the poet lover of beauty, worshipping at the shrine of refinement and art, finds in the less common specimens of artistic photography food for the highest thoughts, and sources of the most ennobling emotions. Such is the art we, as members of photographic societies, have the privilege of training through its infancy, and educating for the glorious missions of its coming manhood.

I think it is high time that this young giant, photography, should learn that, apart from its wonderful and invaluable qualities as a scientific agent, and, high above the perfections of manipulatory or mechanical details. which, after all, are but means to an end, it should prepare to take higher rank with the loftiest and most humanizing of intellectual tendencies as *a Fine Art*.

The arts in their highest state of progress indicate the refinement and opulence of a nation, and are then termed fine arts. This term is at present held to include poetry, painting, music, sculpture, and architecture. To this list there is no just reason why we should not add photography, for in whatever way we define the perfection which is understood as constituting the claim of any art to be called fine, our art can show, either that it already has such qualities, or that such qualities are within its reach, or that there is very reasonable hope of such qualities being acquired. In either case there would exist no fair argument against its claim. Every branch of the fine arts were as much fine arts in their infancy as now. else we are without fine arts; the utmost stage of perfection. or the absolutely highest state of progress, being yet unreached in either of the five arts I have named as fine. I therefore think such facts as are mere indications of the infantine state of photography should not be advanced as arguments against its rightful claim to so honourable a position.

To enforce this claim we must look to our practical operators. The evidence of the eye is better than that of the ear. One member of this valuable society, in bringing forward a single production expressive of real artistic power, sentiment, or feeling, would find in its silent eloquence a more able pleader for the recognition of his art's high value, than a whole army of such poor advocates as you now honour with your attention.

Believing this, I have always, when speaking of art in connection with photography, endeavoured to give my remarks some *practical* value; confident that in calling attention to the more simple or mechanical of pictorial principles, I should have the better chance of enlisting in the cause such allies as would do battle for it with their chemicals and apparatus, rather than with their pens or speeches. Not that I undervalue the æsthetical in art, or think feeling, imagination, or sentiment of less value to the photographer than to the painter; but because I know that the lesser must precede the greater; the seed the harvest. There are those who think the corn already ripe; but they are not many. There are others who believe the soil to be barren ground in which such seed can never grow; these are more numerous. The fact is, the ground is new and strange; *has been neglected, and contains some weeds;* but only requires our operators, societies, and journals, to put their hands to a plough already in the furrow. To do so we must endeavour to urge upon our operators the importance of a practical acquaintance with the rules of art.

There is plenty of art in the *mouths* of our photographers, but there is very little of it, as a rule, in their works. Like Hood's poor fellow who, with victuals always in his mouth, sadly wanted a belly-full. Loose talk about art has never been a very scarce commodity, I'm afraid, but it has certainly always been a mischievous one. With no other aid than a good memory, you may *talk* art or poetry by the hour, but to *feel* either, you must do more—you must *understand* it. It is only those who feel art whose works display genuine pictorial excellence; and it is seldom indeed that any feel art who do not also understand it, even although they may be by no means eloquent in giving to such knowledge verbal expression. The importance of this suggestin may be found in the character of this year's critiques upon the Photographic Exhibition in London.

I have just been reading a series of remarks in some daily and weekly papers. Nearly all of them, directly or indirectly, denounce its claims as a fine art, and at the same time evince the most profound ignorance of its resources, powers and improvements. To understand only one side of a question is said to be a good way of avoiding prejudice, but the critics I refer to, possess such an advantage in a more eminent degree—*they understand neither*. For instance the *Illustrated London News* says, "judging from the appearance of the various works produced, we should be inclined to conclude that the new art had reached its limits, leaving nothing further of importance to be accomplished. As a rival" (?) "therefore, of the fine arts, its powers and resources may be considered as known quantities, and we are still of the opinion which we have always entertained, that as far as the estimation of the real lovers of art goes, the palette and easel have nothing to fear from the camera and darkened room."

This critic has evidently made up his mind, and delivered judgment, without hearing a single witness.

* Read at the meeting of the Photographic Society of Scotland, on the evening of Tuesday the 12th.

Again, *The Times* tells us that "it is as well that the domain where photography ends should be so sharply and certainly fenced off as it is from that where art begins," and adds that "the proof of this separation is afforded by the conspicuous failure of all the photographer's attempts to make pictures."

Now is not *this* a pretty piece of argument? My new cook who took her place among my domestics, without sufficient knowledge of the duties belonging to her office, spoils my dinner, and I tell the guests her failure is a proof that it is impossible to produce a properly cooked joint.

I cannot attempt to reply to these and such things in my present paper, nor, with my present audience is it necessary to do so, but whether we have to deal with critics who believe because they always did believe, or denounce because they don't and won't understand, your practical man's works are in either case the best arguments to advance against them. Prove to the public eye that photographs *are* pictures, and we thus enlist in our cause that mighty monarch called popular opinion, before whom all this cant of criticism will become hushed, and all these dogmatic censors bowed in humble deference. We cannot convince these critics, perhaps, for their closed eyes and stopped ears place them beyond the reach of evidence or argument, but we can deprive their oracular dogmatism of its influence by the exhibition of our seccessful results.

If they point out the flat, adhesive character, of some hard, map-like landscape; place before them another full of space and ærial effect, *produced with as much ease and with the same appliances*, and show them that while the one was produced by a mechanical operator, the superiority of the other had its origin solely in the brain of its producer. If they deride pictures without roundness, or relief, hard of edge, with harsh black patches for shadows, and the high lights swallowed up by masses of glaring white paper; show them another, produced as before with equal appliances, in which the image is soft and round, with transparent shadows, and beautifully delicate half tints, gradating almost imperceptibly from the real high lights into the deeper tones and reflections of more retiring surfaces. They *can't* escape such arguments as these; and so the truth will ultimately triumph, and photography be raised in public estimation as an art in which, *however easy it is to do a little*, only artistic feeling and artistic knowledge can secure artistic results. *They* say it can't be done, *we* say it can; *they* speak in the thunder of the public press, *we* in the whisper of class journals and comparatively unknown societies. Our whisper, therefore, can't compete with their thunder in addressing the public ear; *but our works can speak with even more force and effect than they can command to the public eye.* I, therefore, again repeat that it is to our practical men that we must look for the art's real upward and onward progress.

(*To be continued.*)

Photographic Tourist.

PHOTOGRAPHY IN JAVA.*

ACCOUNT OF A SHORT PHOTOGRAPHIC RAMBLE THROUGH THE INTERIOR OF THE EAST END OF THE ISLAND.

Our first trip, after getting the cyanide, was to a hill in the neighbourhood, at a small elevation, though commanding a fine view of the valley of Ngantang, and which we took as a panorama in three views, it being too extensive for a single picture; we were very lucky to get some fine lowering clouds in the mountain range in the background, which, together with the sun illuminating some portions of the view, and others being in shade, had a very fine effect.

Each of the three plates succeeded perfectly on the first trial, with an exposure of fifteen seconds for the first, and eighteen and twenty-two for the others, owing to the decrease of light, as the sun had set by the time we had packed all up, the short twilight allowing us barely time to get home before it was quite dark.

In going and returning, we had to wade through a small river, rather above our knees, as there was no bridge without going some miles round; from it we filled a bamboo tube with water, and carried it up the hill with us, knowing we should get none there.

During one of our excursions at this time we tried the slanting diaphragm, recommended in "Sutton's Dictionary," by which the sky receives so much less amount of light than the foreground, giving the contrast with much greater truth than the ordinary diaphragm, with which it is difficult to take a view where a foreground of dark trees and a distance of mountains rendered blue by atmosphere, are required to be produced on the same plate.

Although we are rarely troubled by the many minor annoyances of the collodion process, such as foggy bath, spots, development stains, &c. &c., still we sometimes have our troubles, as what photographer has not, even in the more easily workable climate of England. About the time I write of, we were on one of our trips in the neighbourhood, very much bothered by not being able to obtain the slightest density in the negative, with any amount of exposure, though this only lasted for a few days. Again, shortly after, on taking some stereo views, every plate showed a very faint kind of stain on the part that touched the bottom of the slide, therefore spoiling all effect of clouds in the sky part of the picture. Many would perhaps not care about this, but with Indian ink or black varnish black out the sky, and so hide the imperfect part; but we have long had an aversion to that patch of white, which passes for sky in so many of the stereographs offered for sale. We examined our slide, thinking perhaps it was wet from the drainings, but found the plate only touched at the corners, therefore it could not be that; and after trying every remedy we could think of, such as a strip of blotting paper to prevent the accumulation of silver at the bottom of the plate, well draining it, &c. &c., we were obliged to have recourse to our other nitrate bath, when the effect ceased entirely, and things went well again; several days were spent in rambling about, taking every choice little bit that attracted our attention, until we had exhausted the place for several miles round; after which we proceeded on our way to Malang, a place resorted to for its beneficial climate by invalids, ; on the way we stopped twice, to take some pretty river views, introducing the wild ferns, which look very well in a photograph; also a mountain pass, the rocks at the side being covered with wild bananas and bamboo.

Half way to Malang we stopped at a place called Batœ, where we had hoped to get a view of the Ardjuna, a large volcano with the smoke issuing from the crater; but on rising in the morning, we found the sun just peeping from behind the mountain, and falling right into the mouth of the lens; this would not do, so we waited until evening, but shortly after ten clouds gathered rapidly over the mountain, and by about midday it was entirely covered, and remained so until night. As this was invariably the case daily, we gave up the idea, and started the next morning for Malang, where we arrived at 12 o'clock, just in time for tiffin, there being a good hotel there, which was a great treat to us, having had for some time to put up with what we could get.

As there was a good post road from Malang down to the seaport of Pasoerean, we hired post-horses for the journey, taking in the carriage our apparatus for photographing some ruins on the way down, sending the heavy portion of our baggage in carts. The ruins being only one post about six miles on the way, we arrived there about 7 o'clock, and at once took a picture of the small temple, which was so surrounded by a species of tree, sacred to the Javanese, that we were obliged to crowd it into the plate, as we could get no distance away, without having several boughs close in front of the lens, and the natives would on no account allow a branch to be touched. The next subject, in the immediate neighbourhood, was a gigantic figure, carved out

* Continued from p. 92.

of a single block of stone, being one of the finest specimens of the ancient Javanese sculpture, another figure representing the head of an elephant, with six hands was the next; this concluded our morning's work, which we were not sorry for, as the sun was getting too powerful to be pleasant, the place being situated in a much lower district than where we had previously been working. After repacking our things we once more started, and arrived by noon at Pasoerean, after after having spent an agreeable two months tour, and made a nice collection of some twenty-five to thirty views of each sort, stereoscopic and otherwise.

As many photographers in India and other tropical places might perhaps be somewhat benefitted by a few remarks regarding our experience, I will make a few notes on our materials, and mode of working, having already detailed our apparatus for travelling. First, regarding collodion, we have obtained some from nearly every celebrated maker in England, and after a deal of disappointment found invariably that nothing like sensitiveness was attained, with any of them, so we have for a considerable time manufactured our own. The pyroxyline in the ordinary manner, Hardwich's formula, having given us the best result, making it only in small quantities as we require it, as it is much the better for being newly made. The solvent in proportions of 5 parts of ether to 1 of alcohol, the bulk of the alcohol 6 parts more, being added as the iodizer. This we have found by a series of experiments to be the best proportions, though during a late visit to England, I failed entirely with it, finding it very deficient in sensitiveness, compared to other collodion, while here we find on the contrary, that it gives pictures in a third of the time of the ordinary ethereal collodion, both being made of the same materials. For an iodizer, *iod. pot.* is decidedly the best, cadmium giving a ropy sort of film, a a proportion of bromide is also necessary whether for negatives or positives. As developer, iron certainly gives the best results, intensifying with pyro if necessary, as if pyro is used alone the chances are, that the action of light will be reversed at the moment of completing the negative, having for a long time been annoyed with similar results, in nearly every case prior to our using iron. The best nitrate bath, made with the ordinary 30 grains fused nitrate of silver acidified by adding half a drop of nitric acid to an ounce of bath, and iodized by allowing one or two large plates, coated with iodized collodion, to remain in it for a night. This bath rarely gets out of order, as the evaporation always balances the amount of silver taken out, making the addition of fresh nitrate unnecessary, As regards cameras it is difficult to say which is best suited for a hot climate, as most of them go to peices, through the alternate changes of heat and damp. If the metal cameras advertised in our last *Photographic Journals*, turn out what they profess, they will be one of the greatest boons to Indian photographers.

After going through a course of dry processes, from the albumen on glass, to the raspberry syrup, we have come to the conclusion, that in a country where coolies can be had on the shortest notice, that the certainty of the wet process, outweighs all the advantages in portability of the dry.

With these oft repeated formulæ, I will bring my paper to a close, hoping that some one of the numerous travellers that photography attracts to foreign places, may gain some small benefit from my experience. WALTER WOODBURY

Java, October 30th, 1860.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

THE fifth meeting of the session was held in the Society's Hall, George Street, on Tuesday evening. Mr. T. B. JOHNSTON in the chair.

A paper, by Mr. Maxwell Lyte, detailing the method of positive printing so successfully adopted by him, was read to the meeting by the Henorary Secretary.

Mr. WALKER read a communication from Mr. Wall, of London, on the subject of "Art Photography" (see p. 125), in which the author pointed out the claims which photography had to be classed among the fine arts, and the means by which this position might be best attained.

On the conclusion of the paper—

Mr. HARVEY, R.S.A., while expressing the great delight he took in photography, stated the views which occurred to him as to the limited domain of photography, and the difference which would always exist between the pictures of an educated artist and a photographer.

He was followed by various other members, and an interesting discussion on the subject took place.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 13th March, 1861.

EVERY now and then the hopes of those who look to the realization of photography in natural colours are raised by some new result, which, if it does not fully solve the great problem, at least encourages the expectation that we shall, in time, arrive at it. The eminent chemist Böttiger lately exhibited some very interesting coloured proofs at a sitting of the Congress of Königsberg. A violet-coloured picture is obtained by causing paper to imbibe a concentrated solution of the double nitrate of uranium and potassa, and afterwards passing it through a solution of chloride of gold. If the latter salt is replaced by nitrate of silver, a brown red image is obtained. The oxalate of the sesquioxalate of iron yields a yellow proof which turns black in nitrate of silver, or brown by chloride of gold. A blue grey hue is obtained by sensitizing the paper in a solution of 6 or 7 parts of nitro-prussiate of soda, in 100 parts of water. A brown hue is produced by bichromate of potassa.

M. Böttiger has also modified M. Niepce de Saint Victor's process of transferring engravings by means of iodine Instead of exposing them to the vapour of iodine he immerses them in a bath containing 35 ounces of water, 45 grains of iodide of potassium, and 15 grains of sulphuric acid. The hydriodic acid formed is doubtless decomposed, for the iodine collects upon the fatty matter of the ink, as bromine, in analytical experiments, collects together in ether. After the immersion has been continued a sufficient length of time, and the solution has thoroughly penetrated the paper, it is removed and washed, then dried between folds of blotting paper, it is then placed on starched paper and submitted to pressure. In this manner a very faithful negative is obtained, but unfortunately, also very fugitive, which, however, can be fixed, if of sufficient importance.

A new mode of producing chlorine is due to the researches of M. Laurens. It consists in decomposing chloride of copper by the action of heat. The operation is conducted in the following manner. Chloride of copper is prepared in the usual manner, either by dissolving oxide of copper or native carbonate of copper in hydrochloric acid, or by the double decomposition of sulphate of copper and chloride of barium. The solution of chloride of copper obtained is evaporated and submitted to crystallization, then the crystalline mass is mixed with sand and perfectly dried (probably in a reverberatory furnace). The dried mixture is introduced into retorts similar to those employed in the fabrication of gas: if these retorts are of iron, they are lined with a coating formed of a mixture of clay and carbon, to isolate the metals. The chloride, heated strongly, is decomposed into *chlorine* and protochloride. The residue of the preparation of chlorine, *i.e.* the protochloride, is not lost. It can be again converted into chloride by the oxidizing action of the atmosphere in presence of hydrochloric acid. Having thus obtained the regenerated chloride, the operation is repeated as before described, and the circuit may be renewed indefinitely.

The advantages presented by M. Lauren's method,—which is analagous in principle to that proposed by Mr. Dunloyn Tennant—are chiefly the following: an economy of one half in the employment of hydrochloric acid, regeneration of the compound by a single direct operation. But possibly an objection may be made to the high price of the copper: numerous risks of loss are to be feared, either of the chloride during its decomposition, or of the chloride or protochloride in the unavoidable removals. There is also another consideration, which is, that in establishments where the chloride is produced, the handling of considerable quantities of chloride of copper will produce a dust which must prove injurious to the health of the workmen employed. What may be said, however, in its favour is, that this very interesting process is admirably adapted for the laboratory, as it readily furnishes dry chlorine without requiring a fragile and cumbersome apparatus.

In the course of his very beautiful experiments on the production of ice by the agency of ammoniacal gas, M. Carré has observed that brass immersed for several hours in a weak, cold ammoniacal solution, becomes as friable as clay. Iron, steel, and lead, under similar circumstances, remain unchanged. During these experiments it was also observed that ammoniacal gas, escaping under a pressure of one or more atmospheres, assumes a decided blue colour, similar to that of the smoke of certain woods, and of fuming acids.

Acetic ether is apt to be contaminated by free acid and alcohol; by adding water and magnesia to such ether, both the acid and the alcohol are separated at the same time; but as there will be some loss of ether by its solubility, as much salt as will dissolve in the liquid is added. The chloride of sodium prevents the solution of ether in the water, without eliminating the alcohol. The ether which separates from the salt-water is pure and anhydrous, with a density of 0·89.

Dr. Kursak proposes the employment of tannin as an antidote to strychnine; the dose to be one drachm of nut-galls to one grain of the alkaloid. Any astringent substance at hand may be substituted for the tannin, such as acorns, oak bark, chestnut bark, &c. Acids and spirituous liquors must be avoided.

LARGE STEREOSCOPIC PICTURES, AND NEW STEREOSCOPES.

Sir,—As it seems a sort of movement is now in progress having for its object the increase in size of stereoscopic pictures, and as a great number of stereoscopic cameras have been recently made for plates of 9×4, 8½×4, 8×4, 8×3¾, and 7¾×3½, perhaps a few remarks on the subject may not be ill-timed.

There has been for some years a general desire to introduce more subject into stereoscopic views than they have hitherto contained, but every attempt to do so has failed, because the present small stereoscope, with prisms or lenses of six inches focus, is not calculated for pictures larger than three inches square, and that focus having been universally adopted, it would perhaps be hopeless to attempt to induce the public to purchase other instruments for the purpose of viewing slides of a more expensive description. The generality of stereoscopes in present use are not rightly made, neither have they been furnished with sets of object-glasses of different powers, to enable us to exhibit and view pictures of various sizes at pleasure. Every instrument should be accompanied with two sets of prisms, being respectively of 6 and 8 inches focus, and prisms of 9, 10, and 12 inches focus should be available, if required by the purchaser. Each set of glasses should be fitted into a frame, which could be slided into a groove in front of the stereoscope, so that one set could be taken out and another put in, with the utmost ease. The stereoscope itself should be of the simplest description. A piece of mahogany 12½ inches long, an inch broad, and a quarter of an inch thick, should at one end carry a light frame to be held close to the eyes, and to receive the eye-pieces, and at the other a cross-piece to rest the slides against. This cross-piece should be made moveable, so that the spectator could slide it over the mahogany bar, and bring it and the slide as much nearer his eyes as he might wish. A handle might be made to screw into the bar and be unscrewed at pleasure. The cross-piece for the slides should be furnished with a screw underneath, to fix it at any distance required. No partition to prevent the right eye seeing the left picture, or the left eye seeing the right, is necessary, and the instrument thus constructed is the *ne plus ultra* of simplicity.

With a set of eye-pieces or prisms of six inches focus, we can view a slide mounted with two pictures of three inches square. For slides mounted with pictures of larger size, we require lenses or prisms, the focal length of which is equal to the length of the two pictures placed in contact with each other. Slides with pictures 4 inches square, or 4 inches long, require prisms of 8 inches focus, and with pictures of 4½ inches square or long, prisms of 9 inches focus. But when the pictures are taken with a lens of 7 inches, they may be seen advantageously with eye-pieces of even 18 inches focus.

But we must carefully bear in mind that small stereograms taken with lenses of 4, 4½, 5½, and 6 inches focus, should not be viewed in stereoscopes the object-glasses of which are more than one-fourth longer in focus than the focus of the lenses wherewith they were taken. If we do, we shall find that the minute details of the pictures are lost, or so diminished as to be ineffective. If, for instance, in stereograms taken with a 5 or 5½ inch focus lens, figures have been introduced whose features are perfectly discernible in the 6-inch stereoscope, on transferring the slides to an 8 or 9-inch stereoscope, we shall not be able to recognise them distinctly. If, then, we take care that the eye-lenses or prisms are not more than one-fourth longer focus than the lenses by which the pictures were taken, we shall adopt a safe rule, and preserve the full extent of stereoscopic effect. This rule, however, will be readily seen to operate so as to limit the size of the stereogram.

Pictures taken with lenses 4½ inches focus, must—in order to appear with the proper amount of effect—be viewed with prisms or eye-pieces of 6 inches focus. Such pictures, therefore, should not be more than the usual size, 3 inches square. Pictures taken with 5½-inch lenses should be viewed with glasses of 7½ inches focus, and those taken with 6-inch lenses, with glasses of 8 inches focus. If, however, 5½-inch lens-pictures are viewed with 8-inch glasses, they do not lose very much; indeed, not at all, if this lens be used for near objects, and the 6-inch lens for distant ones. I should, therefore, class them with stereograms taken with 6-inch lenses, and take both 4 × 3¾. This size would require glass plates of 8½ × 4, containing 33 inches superficial.

I would, therefore, recommend to all photographers who wish to take stereograms including a wider angle, to work with 5½ and 6-inch view lenses, upon plates 8½ × 4, and to use stereoscopes for their exhibition mounted with prisms of 8 inches focal length. This arrangement would leave the present stereoscope and its slides as they now are, and those who now prefer that size can get all they wish with 4½-inch lenses. They can even take views 3¼ × 3 upon the usual stereo-plates, and mount them for the larger stereoscope, or one with 6½-inch object-glasses, if they so wish.

In purchasing stereoscopic view lenses of 5½ and 6 inches focus, it must be ascertained that they will cover the field required. I mention this, because I have met with lenses which will not do so. I possess a pair of most admirable single lenses by a French maker, of 5½ inches focus, which will not give a circle of more than 5 inches diameter, owing, I suppose, to the mode in which they are achromatised. They were intended specially for stereoscopic work, and to give pictures of 3 inches square only. But a really good 5½-inch focus lens should give a square of 3¾, and a picture of 4 × 3¾. A pair of Goddard's 5½-inch lenses in my possession will cover a 5 × 4 plate well. Their diameter is 1⅜, which in my opinion is a great advantage where a ⅜ths aperture is used for instantaneous work. Six-inch lenses should have a diameter of an inch and a half.

Trusting that these remarks will tend to produce uniformity in the size of glass plates and stereo-pictures on an enlarged scale, I respectfully submit them to the judgment of your readers. I am not aware that what I have said will be found in any publication on the subject, but I think that those who will take the trouble to test the accuracy of my statements by actual experiment, will find them correct.

The subject of stereograms taken with a lens of 7 inches focus I shall not now enter upon. They involve considerable expense, and are perhaps best taken with separate cameras, or, at all events, upon separate plates. I will only remark, that when viewed in a 12-inch focus stereoscope, their effect is really fine. Views taken with lenses exceeding 7 inches focal length, are more suitable to the reflecting than the lenticular stereoscope. R. A. R.

COLLODIO-ALBUMEN PHOTOGRAPHY.

DEAR SIR,—In a recent number of the NEWS, your correspondent "G. P." has called attention to the fact, that my observations in reply to his previous letter are not immediately directed to the question, as to the possibility of coagulating albumen at any temperature when it exists as a thin layer upon a collodion film. I admit that I did not confine my remarks exclusively to this particular question, for the simple reason that other points of equal or even greater interest were touched upon by your correspondent himself, and are associated with the inquiry.

The primary question, for instance, "as to whether sensitiveness is dependent or effected by any structural change in the albumen" constitutes an essential element in the determination of the best method of practising collodio-albumen photography. It may be true that in our present state of chemical knowledge it is impossible to define an exact limit between chemical and structural modifications; but it is equally so, that the photographic bearing of the subject constitutes a sufficient justification for the further investigation of the subject. The observations made by Dr. Riley, Mr. Hardwich, and myself, implied a common understanding that additional knowledge must be acquired before a decisive conviction could be arrived at, and Dr. Ryley invited discussion with the remark that his only reason in bringing his paper before the society was to *elicit* truth. "G. P." however, desires to direct attention more especially to the erroneous notion involved in the supposition that heating and drying the plate coagulates the albumen. "The question," he observes, "whether the film of albumen can be coagulated by drying the plate, at any temperature, however high, is of too much importance to be passed over slightingly, and I am very sure it cannot to left in more able hands than Mr. Davis's, if he will experiment upon the subject without bias." The above remarks do not define as to whether the film of albumen is presumed to be superimposed upon the collodion film, or to rest directly upon the glass. As it is always desirable to study any particular reaction under the simplest condition, I have given a little attention to the inquiry, under the latter circumstances, during the interval that has elapsed since the publication of the letter from which I have made the last extract. The exact method that I pursued was as follows:—I first covered a glass plate with white of egg, drained off the superfluous quantity from one of the corners, introduced it into a Taylor's hot-air bath previously heated to about 180° Fah., and there allowed it to remain for about ten minutes. After this treatment the plate did not exhibit any appearance of opacity, and, therefore, no perceptible indication that the film of albumen had suffered coagulation. It naturally occurred to my mind that the tenuous condition of the film might be the cause of the absence of any appearance of coagulation, a slight abrasion of the surface, proved however, the contrary. If the above experiment may be considered conclusive, and it can be shown that the same reasoning holds good with respect to the albumen within and in immediate contact with a collodion film, I must necessarily agree with your correspondent, that I entertained and expressed an erroneous idea when I stated that both the structural and chemical properties of the film must have been altered by the *process of coagulation*, because my albumenized plate had been submitted to a temperature sufficiently high to set white of egg in its ordinary condition. The reason that the albumen is not set by the treatment referred to appears to be this: a considerable portion of the water which is combined with it in the normal condition of the white of egg is separated by evaporation before the film is heated to the requisite temperature. In other words the water is driven off at a lower temperature than that necessary to produce insolubility, and such being the case, the dried white of egg may be exposed to a heat of 212° without any alteration of its properties. It has already been recorded in the report of the Experimental Committee of the South London Photographic Society, that if we immerse a film of albumen resting upon glass into boiling water, we wash it therefrom, and consequently obtain no evidence of coagulation. This probably arises from the circumstance that small quantity of albumen present is largely diluted with water before the necessary elevation of temperature is reached. We now pass to the effect that is produced by the action of a cold solution of gallic acid upon a similar film to that under consideration. In this instance, we find that after a short immersion a slight opacity is produced, the tenacity of the film to the glass is destroyed, and the compound may be freely washed from the plate. If, on the other hand, the albumenized plate be immersed in a solution of nitrate of silver, we find an immediate opacity produced, indicative of the formation of albuminate or albumino-nitrate of silver, other insoluble metallic salts of the precious metal, but probably no change that can be strictly designated coagulation. In this instance we find that the normal tenacity of the film to the glass is not destroyed, but that it may be washed freely with an abundance of hot or cold water without the displacement of that portion of the layer in immediate proximity to the plate, from the surface of the glass. It will be noticed that the above experiments have reference to albumen resting upon the glass itself, but when we pass to the consideration of the latter within the interstices of the collodion film itself, the inquiry necessarily becomes more intricate and difficult. But assuming from analogy that the above reasoning is applicable to the layer of albumen resting upon an excited collodion film, we can readily understand that its removal would be effected by cold and boiling water, or a solution of gallic acid. I do not find, upon the other hand, that by treating a *washed albumenized plate*, from which the whole of the free nitrate of silver has been previously removed, gains any increased sensibility by being treated with the solution of gallic acid, although there is a difference in the colour of the resulting negative. As a similar result accompanies the combination of some saccharine substances mixed with the albumen solution, we have reason to attribute each alike to a chemical cause. When, upon the other hand, we treat a washed albumenized sensitive plate with a solution of nitrate of silver, we obtain increased sensibility, inasmuch as we convert an insensitive into a sensitive albumino-nitrate of silver compound. If, therefore, we desire to increase the sensibility of a plate prepared according to my suggestion in the report above alluded to, we have only to dip the plate in a weak solution of nitrate of silver, wash, dry, and expose it as soon as convenient. I say as soon as convenient, because we shall find that we have destroyed its permanent keeping properties.

Although we cannot but feel that we have much to learn upon the subject, yet we may reasonably hope that the theory advanced by Dr. Ryley, the distinction between drying and coagulating albumen, to which "G. P." drew attention, together with the recent investigations that have followed thereupon, have not been altogether ineffectual in contributing to a more correct understanding of the principles of collodio-albumen photography.

THOMAS SEBASTIAN DAVIS.

Photographic Notes and Queries.

Alkaline Toning and Permanent Photographs.

Sir,—Under this head I purpose to address a few observations to you, and through you to the photographic world at large. I read in this week's News that alkaline toning is objected to on account of its *blistering the fingers.* Now, sir, I write this with the utmost respect for the author of the above remark, but photography is not the only profession in which votaries will disagree, and using the alkaline toning myself, knowing many others who work it, and not having heard one single instance of so injurious a result to the operator, I feel bound to take up the cudgels on behalf of our favourite method of toning and fixing. I have had the fingers turned yellow with the gold, but the raising of pustules, rather than ascribe it to the toning, I should lay it to the unfortunate flesh of the individual.

"The permanence of photographs."—In conversation the other day I was questioned on the above, and in very distinct terms informed that our pictures were but transient ones, that *they faded.* It is a bold assertion, nevertheless, I am justified in making it, but a *photograph is permanent.* Properly attended to there is no doubt on the subject; the free nitrate washed from the proof before immersion in the gold, washed from gold before being fixed in *fresh* hypo, and then after having been plunged in water, placed on a sheet of glass washed under a tap with a piece of cotton wool, changed frequently for, say four hours, in running water, then for four hours more in several changes of lukewarm water, and I venture to assert, that such treatment ensures the permanence of the picture. Let those who doubt try, and "be not persuaded, but convinced." One word more on the pictures which undoubtedly do fade; for them the public have themselves alone to thank; they will have *cheap* photographs, they delude themselves with the happy belief that a photograph "is all profit, only costs this, we will give that," and the result is the wholesale production of *things* which fade before they are sold, a disgrace alike to purchaser and seller; as for the instrument or machine who "executes" (!) them, I leave him to the tender mercies of his conscience—when it awakens!

Let me, in conclusion, ask the public to give a fair price for pictures, and there will be no longer complaints on the unstability of the productions of our art! A proof paid for is a proof permanent; but a "representation" at *per gross*, is an "unfortunate," plunged with all its free nitrate on its face into a *boiling* mess of hypo, acid, sulphur, &c., &c., *ad lib.* Apologising for so long a note, and enclosing my card, I am, sir, yours respectfully, Phos.

Alkaline Toning.

Dear Sir,—I was reading a work the other day on the preparation of salt, when my attention was drawn to the following, which, in my opinion, must exercise a deleterious effect, and perhaps be the cause of many of the faults complained of by numerous operators in this process.

In the preparation of salt from the springs it is put into a large pan and boiled, *that* prepared for the table, called common salt, and sold in pyramidical shapes, being of a finer quality, is boiled much faster, and contains (in consequence) when sold *a considerable quantity of lime.*

Now, in the last wash given to the prints before toning, it is recommended to "place them for three or four minutes in a bath containg a quarter of an ounce of *common salt* to the pint of water," some operators say "one ounce of salt, and water *ad lib.*"

Now, from experiments I have made, I find, that *common table salt,* when used in the quantity of an ounce to the pint, *causes* a film over the print, and renders it very difficult to tone, in some cases the toning bath has no action on it whatever. (The use of such a bath we know is to convert any trace of silver into a chloride.) This film is called chloride of silver, erroneously, I think. On immersion of the prints in the salt bath they at once become of a golden red colour, and if left in the bath for five or six minutes, sometimes less, become covered with a white deposit, which will *not* rub off; sometimes it is but slight, at others very dense. When slight, I have frequently got an uneven tone, being spotty, and of a dirty brown. When dense, I get no tone at all, and I find that those prints speedily spoil.

Flake, or rock salt, or pure chlor. sodium gives very different results. On immersion in a bath of this, 1 ounce to the pint, the print takes a clear red tone, but no deposit occurs, and on immersion in the gold bath,the toning proceeds evenly and well, and such I now always adopt.

In conclusion, I would ask those operators who complain of uneven toning spots, &c., to try both kinds of salt, and judge for themselves.

My attention has been drawn lately to the remarks upon the argentometer. I bought one three years ago of H. Francis (3s. 6d.) On trying it to-day on an old sensitizing bath, it registered 30 grains nit. argt. to the ounce aqua. On testing a sample of the same bath with Bolton's test by chlor. sodium, I got 29 grains to the ounce. I have always found the little instrument pretty correct, sufficient, at all events, for sensitizing baths for paper. Apologising for troubling you, I am, dear sir, yours truly, W. H. Warner.

Ross, March 7, 1861.

The Tannin Process.

Sir,—The merits of the "tannin preservative process," mentioned in page 119 of your last number, will soon be widely canvassed, and "failures" and "successes" will soon occupy the attention of your readers. The announcement of its discovery and value, coming from such a trustworthy source, and such an exact experimentalist as Mr. Hardwich, will doubtless induce many who have been unsuccessful with the ordinary dry processes of Taupenot and Fothergill, to try their hand at this. I have not yet seen the new edition of "Photographic Chemistry," and am. therefore, in entire ignorance of the mode of manipulation therein recommended, but I venture to send you an account of my first experiment, which has yielded me very excellent results. The point of information from which I started, was the fact mentioned in one of your contemporaries, that the process consisted of an application to the sensitized collodion film of a solution of tannin, which was simply dried on its surface. From the nature of this solution I at once saw the necessity of thoroughly washing off the free nitrate previous to applying the tannin, which in combination therewith would otherwise soon set up a decomposition fatal to that degree of stability so requisite in every keeping process of any value to the tourist. After removing the plate from the bath, I washed it in a solution of a teaspoonful of common salt in two quarts of pump water. The plate was stereo size, and I washed it with a wave-like motion in five or six changes of this water, allowing it to remain altogether therein about 2½ minutes. On taking it out I applied the pneumatic plate-holder. and poured on its surface about an ounce of distilled water to get rid of the salt solution. I then dosed it with as much of a filtered solution of tannin (one grain of this to one ounce of *distilled* water) as would well cover it, and allowed it to remain for about a minute, then drained and dried. Plates thus prepared are very sensitive (a little more so than Fothergill's, and develop rapidly, and without stains. They promise also to keep well; I have kept them for about a week without any perceptible deterioration. After exposure soak the plates for two or three minutes in a little distilled water heated to a temperature of about 100° Fahrenheit, *i.e.*, so as just to feel warm to the hand. I used the ordinary pyrogallic developer. I do not give you this as embodying the best proportions, or the best mode of manipulation, but merely as the result of a first and highly favourable experiment.—Yours, very truly,

Willand Ford, March 2, 1861. H. Fitzroy Pelham.

Yellow Glass for Dark Rooms.

Sir,—Having had occasion lately to purchase some glass for a photographic dark room, I ordered it of a respectable house in London, specifying it as "orange-coloured glass for photographic dark room." The material received, designated in the invoice as "orange-coloured pot-metal," appeared to me of rather a light colour; I therefore exposed a sensitized collodion plate underneath a piece of the glass to the northern sky for 20 seconds, and developed it. The result was, a fine dense deposit of silver over the whole plate, except a portion of the middle, where a strip of brown paper was on the orange glass. I, of course, returned the glass as useless, and asked for another sample, and and at the same time I wrote to two other London houses for samples of glass for the same purpose.

On obtaining these three samples—the first, *stained* glass of a rich orange colour, at 2s. the foot; the second, a darker reddish orange glass, at 1s. 3d. the foot; the third, a bright yellowish orange, "pot-metal," at 1s. the foot.

A small square of each of them was let into a piece of board, and a sensitive plate was exposed underneath it to the northern sky for 30 seconds.

A print from the developed plate I enclose. No. 1 developed a deep black; No. 2, nearly the same, but not so dense; No. 3 showed no trace of the action of light, not even an appearance of fogging.

These facts may be useful to your readers, as they show the necessity of care in the selection of glass for photographic dark rooms, even when the most respectable London houses are dealt with.

It also shows that the deep reddish orange coloured glass is not so effectual a guard against actinic rays as the bright yellowish orange of No. 3 sample, which also admits much more *yellow* light to work by.—I enclose my card, and subscribe myself obediently yours, H. S.

Chatham, March 5, 1861.

[Our correspondent has forwarded to us the print referred to, and also the samples of glass. So far as the appearance is concerned, we should have been led to expect that those marked one and two would have been perfectly non-actinic. We shall endeavour to obtain some information as to the causes in operation. Ed.]

Chloride of Gold from Alloyed Metal.

Sir,—Having some old gold, such as the setting of false teeth, old jewellery, &c., and wishing to turn it into the *chloride* for photographical purposes, but knowing it to be impure, probably containing copper and silver, (I know how to obtain it from the pure metal), I should be glad if any of your numerous correspondents would enlighten me in the refining process.—I remain, dear sir, yours sincerely, J. L.

Green Rig Villa, Blencogo, Wigton, Cumberland.

[If silver be present it will be thrown down as a flocculent precipitate in dissolving the gold in nitro-hydrochloric acid. To remove copper—as soon as the gold is dissolved, dilute the solution freely with distilled water, and then add a solution of sulphate of iron in the proportion of six parts of iron to one of gold—this will precipitate the gold free from the copper. Redissolve the precipitate in nitro-hydrochloric acid, and proceed in the usual way. We shall enter more fully into these points in the articles on "Photographic Chemicals, their Preparation, Adulteration, &c."—Ed.]

Turpentine Waxed Paper.

Sir,—In reply to some of the inquiries respecting the turpentine waxed paper process, allow me to say I have found it best to buy the paper ready prepared, from Marion and Co. In justice to those who buy, I should add that I have had some very bad paper from them; but the faults arose from causes beyond the control of the preparer, being caused by the metallic spots in the paper, which do not show till the developing solution is used.

I have employed it for stereoscopic negatives with a Lerebour lens, and have some which have produced prints, mistaken for the results of collodion.

I found a *saturated* solution of gallic acid gave me good pictures, when Mr. Sisson's saturated solution, mixed with an equal quantity of water, was useless.

The spare solution can be added to the gallic-acid solution. Discoloured baths are entirely avoided, and the annoyance of a weakening bath is spared.

I believe it is best to excite all waxed papers on a glass slab. Two drachms of aceto-nitrate solution poured on the glass, and spread with a slip of paper, is the quantity for a single sheet, when it appears to be *white* when it must be lifted and turned on the glass, for a minute or two, before transferring it to the washing water.

For the second paper, pour *one* drachm of fresh aceto-nitrate; and after it is ready, drain the slab, and begin again with two drachms.

Unbleached wax is more pure than white, and is practically as good for photographic operations.

Wax is prepared by putting combs into water and boiling them; then separating the dross by straining it through a coarse cloth, or by skimming it off. Of course, the whiter the comb, the finer the wax. I have some given to me by a friend quite white. Yours obediently, J. B.

March 12th, 1861.

Specific Gravity Silver Meters.

Sir,—While the hydrometer question is still afloat, I would say (with your permission) a few words on a modification of the specific gravity method adopted by me for some length of time, which gives for printing purposes results to a quarter of a grain if desired. Proceed as follows:—Obtain a light glass flask, tube, or other convenient vesssel of *little more than one ounce capacity when quite full*, into this measure one ounce of distilled water, then fit a cork with one of the fine glass tubes pencil leads are kept in, through the centre (or simply as a V groove) and adjust it to the neck till the water appears at the top of the tube. Mark its position on the neck at the bottom surface; —Now weigh the whole arrangement in the balance, and obtain the counter-poise in one piece for future use. By substituting the solution of silver under trial, for the water, you will assertain the number of grains per ounce by the extra number of grains it takes to equipoise the vessel. In conclusion I would suggest; *In medio tutissimus ibis.* H.

Photography on Wood.

We have received an interesting letter on this subject, some extracts from which we subjoin. After referring to our allusion to an engraving by Mr. Langton from a photograph on wood, which appeared in the *Art Journal*, in 1854, our correspondent proceeds:—

"Being at that time an apprentice to Mr. Langton, I know all the facts in connection with the subject inserted in the *Art Journal*. The subject was from the original drawing of the moon, made by Mr. Nasmyth, of Patricroft, near Manchester, from which a small negative was copied by the Rev. St. Vincent Beechey, of Worsley, near Manchester, and printed on the wood by that gentleman, which was executed *with difficulty* by Mr. Langton, on account of the prepared surfaces of the wood chipping off very frequently, consequently the redrawing had to take place before proceeding any further in the engravings.

"To the best of my knowledge the photograph engraved was the best for the purpose out of many experiments made by the rev. gentleman, who, at that time, I considered a clever photographer.

"Previous to this there were some engravings on wood in the *Practical Mechanic's Journal*, executed from photographs on wood, which were obtained by loosening the film of the glass positive, floating it in water, and finally launching it on the wood.

"This had the priority of Mr. Langton, whose supposed invention was made known throughout England and the Continent, and the worthy editor of the "Practical Mechanic's Journal" reading of the circumstance, kindly sent Mr. Langton a copy of the above publication containing the engravings from photographs on wood.

"I do not think Mr. Langton has, since 1854 made any further attempts with the Rev. St. Vincent Beechey's invention, nor has he done anything with photography, being too much engaged in the engraving department, in one branch of which I consider he stands unrivalled, that of machinery engraving.

"During my apprenticeship I made several attempts to photograph direct from the camera, in which I succeeded, the subjects being a moderator lamp, stereotypes of which I now have.

"I am now preparing a series of photographs on wood, which are taken direct *in the camera*, and which have not the slightest obstacle in the way of being engraved by any ordinary engraver on wood.

"I will, ere long, forward you specimens for inspection.

"If I mistake not, Mr. Bolton stated, some time ago, in the pages of the News, that he was the first to produce a photograph on wood, which could be executed. Now if that gentleman will give the date of his first success, it will materially assist in discovering as to who first practically made use of photography on wood for engraving purposes.—I am, dear sir, yours, &c. Bennett Lowe."

[We shall be glad to see the specimen to which our correspondent refers.—Ed.]

Talk in the Studio.

Presentation Photograph.—The Sub-Committee appointed by the South London Photographic Society to select a print for presentation to the members, have decided on one of Mudd's well-known photographs—tho picturo being "Coniston Falls," the prize picture of the Scottish Exhibition last year. Perhaps few photographs that have been exhibited embody and combine so many of the elements which go to make a successful picturo as this effort of Mr. Mudd's. It is a striking and sublime subject, combining a bold vigorous foreground, with the turbulent water leaping, tumbling, and frothing over the jagged and broken boulders, with a background in which gradation after gradation of distance carries the eye on to the far-off hills. Not only is tho subject so fine and the view well chosen, but the photography is magnificent. We are tempted to adopt tho Irishman's criticism, who remarked that "thore was but one word in tho language which would express the beauty of a certain actress, and that *mono*syllable was—perfection!" There is not a square inch of tho picture which does not present in itself a study of wondrous detail, whilst the harmonious massing of the lights and shadows and the general breadth constitutes this a most perfect picture. Tho photograph selected last year was one of Bedford's fino views of "Tintern Abbey," by the wet process, and consisted chiefly of foreground effects. This year the picture of a master in the collodio-albumen process is selected, and one in which tho distance is peculiarly charming. We congratulate the members on the judicious selection of their Committee, which thus secures examples of variety of style and process, as well as of tho highest excellence in each.

International Exhibition of 1862.—The designs for the building are now completed and drawn. The extent of grouud covered and the capacity of tho building generally will be greater than that of 1851. Glass and iron will not, as before, constituto the entire fabric, but will be largely used in connection with brick and stone, in the outer walls, whilst iron columns and girders of gothic character will be used inside. There will be a magnificent dome of glass and iron larger in every way than St. Paul's, or St. Peter's at Romo; it will be in fact the largest domo in the world.

Art Committee.—Her Majesty's Commissioners havo invited a number of persons distinguished for art knowledge, to form a committee of advice on various interesting questions related to art. The Duke of Buccleugh, Earl Stanhope, Sir Charles Eastlake, Messrs. R. S. Holford, M.P., Wm. Stirling, S. H. T. Hope, have already consented to join tho committee.

Soane Museum.—Mr. Joseph Bonomi has been appointed to fill the recently vacant post of curator to this museum. The choice is considered by all who know this gentleman's interest in, and fitnoss for, the duties, an excellent one.

To Correspondents.

N. W.—Very excellent views can be taken with positive collodion, and subsequent intensifying; but it is a simpler plan to take them by one process with negative collodion, unless extreme rapidity be important. Either of the processes you name for intensifying will give good results. A mixture of 1 and 2, or 1 and 4, or 2 and 4 will probably give you good results. We have not tried Mr. Fry's method of making the printing bath; but he has used it for years. River water or spring water. The white powdery lines on the shadows of your picture, probably proceed from scum on the top: look to that; a little more acid in the bath may help you. The stop between the lenses should be nearest to the front lens.

F. Lane.—Such specks are not uncommon when there is an excess of nitric acid in a developer. But these you name are apparently reduced in the bath. Filter and add some new solution.

P. X.—About twenty grains of nitrate of silver and twenty grains of citric acid to each ounce of distilled water is a good strength for citro-nitrate of silver to add to a developing solution. The number of drops to be added to the developer will somewhat depend on circumstances; about ten or twelve drops to half an ounce of pyrogallic solution will generally be sufficient for dry pla s, or less if you wish to develop slowly so as to secure abundance of detail without over-developing the highest lights.

J. C.—Opinions vary as to the best distance between the twin lenses of a stereoscopic camera. Where two inches and a half is spoken of as the exact distance, it is on the supposition that this is the exact distance between the human eyes. Where the camera front admits of no lateral motion of the lenses—and none is needed—about three inches or three inches and a half, are better than two and a half, as a little more relief is obtained in distant objects, without much of the effect of diminished size, which a great distance between the lenses is apt to give. In using a binocular lens camera for the production of transparencies, the glasses must be cut: or if it be desired to avoid that, the pictures must be taken at twice, altering the position as in a single lens camera on Latimer Clarke's principle.

H.—The syrup for the dry albumen process will keep some weeks in a cool place. 2. The plates are better excited immediately on cooling the plate, and whilst it is warm. 3. A proper bath must be prepared; it will become gradually discoloured, and may have the colour removed by means of kaolin, or what will cause less risk to the silver bath, citric acid. 4. The plates will keep well a month, probably longer.

J. H. M. R.—We cannot tell you the price of a plano-convex lens three inches diameter, as much would depend on the quality, and the optician of whom you purchase it. Possibly about half a guinea. 2. It is quite impossible to state the exposure required by any plates, as it depends on the kind of lens, the size of stop, the kind of view, the season of the year, and many more conditions. Practice alone will guide you in this respect. Pyrogallic acid is the developer used for Dr. Norris's plates. If your question refer to the printing of transparencies on these plates, a few seconds exposure to diffused daylight, will suffice. See article in this number on the Tannin Process.

G. Mackellar.—It is difficult to say which is the best dark tent or box for developing. Leake's, perhaps, is the lightest and cheapest; Smart's, perhaps, the most complete. Two or three others are now in course of preparation by different makers. We intend shortly to give descriptions of several.

R. R.—The most usual chemical action of light in photographic operations is to darken. In the Daguerreotype process the plate of silver is brought to the blackest possible polish, and having been submitted to the fumes of iodine and bromine, exposed to light, and then submitted the vapours of hot mercury, the impressed image is white, or rather various gradations of white and grey, upon the black plate, which forms the shadowed or black portions of the picture.

D. G. Morgan.—An iron developing solution for negatives may vary in strength according to the requirements of the collodion, the temperature, &c. About fifteen grains to the ounce at the present season of the year, and about ten grains in summer, is about the strength we prefer. In all cases, the amount of acetic acid should at least equal that of the iron. Some very fine negatives that we have seen have been produced by a fifty-grain iron developer. Remember that to obtain the full value of iron, as a developer for short exposures, your collodion should contain a small portion of a bromide as well as an iodide.

J. H.—River water or spring water is referred to.

G. S. S.—It is much a matter of individual taste. Many good operators prefer a stereo lens of 4½ inches focus. Wilson uses one of 6 inches focus. In the new stereo lens you name you have the advantage of both a long and short focus without any sacrifice in either. We prefer it for our own use very decidedly.

No. 35.—The "new discovery" to which you refer is, as you phrase it, a very decided "sell." It simply consists in taking a newly printed wood engraving, and whilst the ink is wet, causing it to "set off" on to another clean piece of paper, and obtain an imperfect duplicate impression. It was exposed in the Photographic News, p. 192, Vol. IV. The Debusscope is a pretty philosophical toy, giving effects something like a kaleidoscope. The slides are coloured diagrams to vary effects.

F. S. C.—No. 9 is out of print, aud reprinting would not be remunerative. We hope to get a few copies from agents. 2. Marine glue is usually obtained at the tool shops. We do not know any special house that keeps it. We got a quantity some years ago at a shop in the neighbourhood of Fitzroy Square, and have not required any since. The manufacturer is Jeffery, somewhere in the Commercial Road.

G. P.—The slip to which you refer desired an answer to be given to "Alpha," which, as you see, was done. We shall have pleasure in proposing you as we there stated. You can send us your name and address, or you can call upon us at the office on a Thursday afternoon. We shall be glad to see you. The next South London Meeting is on the 21st inst. We do not for one moment impute illnatured motives; but your letter certainly appeared to have a captious tone. We have, and can have, no motive but the elucidation of truth, and we feel it is important to eliminate from scientific discussion everything which can be construed into acrimony. If gentlemen who take part publicly in aiding the progress of photography feel that such effort subjects them to criticisms which at least *appear* captious, it will have a tendency to repress such effort. In regard to the question of anonymous writing, we make a great distinction, as we have before said, between personal and public matters. An individual criticizing or public body in *propria persona* stands at a disadvantage sometimes, and therefore does it anonymously; and so long as it is done with truth, dignity, and temper, he may be right. When two persons discuss, the case is different; they should stand on equal terms. Our correspondent will find a communication on the subject of his letter in the present number, which possibly may somewhat explain what he desires. For the rest, we shall be glad to talk to him.

J. C. B.—1. Yes. 2. We don't know. 3. We know of one or two new ones now making; we can tell you better therefore in a week or two. 4. We should not like it for own use.

A Subscriber from the First.—The lines across your plate probably arise from a stoppage or hesitation in plunging the plate into the nitrate bath. The plate must be lowered into the bath steadily without any pause.

Tyro.—Light grey will be the best colour for your background. The best and cheapest material is unbleached sheeting calico which can be had of great width at a trifling cost. Dying would do if the right colour were obtained, and the cloth kept out of focus so as to avoid showing the texture. A very simple plan is to paint it in distemper either a light buff or a light grey, using plenty of size in the colour. Before using, try a patch of it and let it dry; then ascertain the colour it gives on taking a photograph of it. By this means you will ascertain the modification necessary before covering the screen. It would be more durable if painted in oil and "flatted," that is, let the final coat of paint have no more oil than is absolutely necessary, using turpentine instead, so that it may "bear out" flat or dead. This will be a good background for portraiture generally; but it is well to have two; one like that described, and another a little darker. We cannot advise you to have one made in town, as it will be more likely to suit your purpose to do it yourself, or have it done under your own superintendence; besides the risk of injury in carriage.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 133.—*March* 22, 1861.

THE ETHICS AND ETIQUETTE OF SCIENTIFIC DISCUSSION.

We remember being amused some time ago by the order and classification into which a gentleman—himself a member of more than one learned society—arranged the peculiarities of temper which universally, as he stated, characterised the members of different scientific bodies. His theory assumed on the one hand, that the favourite pursuit influenced the temper of the man, or, on the other, that the mental conformation which gave a bias in favour of any particular science was generally accompanied by its given idiosyncracy of temper, and that success in the science was generally accompanied by an augmentation of its accompanying peculiarity of temper. Without following out this whimsical theory, which was accompanied by a few illustrations which seemed to give it some show of truth, we took exception to one case in which we thought it assuredly broke down. The pursuit of one science was stated to be accompauied by a waspish acerbity of temper, and the attainment of eminence accompanied by a degree of quarrelsomeness and dogmatism utterly intolerable. To this we took entire exception, feeling assured that shallowness and ignorance of truth alone could produce dogmatism or quarrelsomeness on its behalf.

It might be an interesting study, however, to the psychologist to consider to what causes is due the fact—happily rare, but still sufficiently familiar to all interested in scientific debate—that an amount of acrimony and bitterness is at times imported into discussions, involving no personal considerations, which is utterly astounding and inexplicable. We think perhaps amongst many causes, there are two chief ones operating in conjunction with natural infirmity of temper. The first, which produces the milder form of acerbity, is simply inconsiderateness, a sheer oblivion of the possible construction cutting words may bear, or the possible pain they may inflict on others of sensitive temperament. The second cause, which leads to the grosser breaches of good manners, is simply ignorance combined with a naturally snarling temper. We believe it is nothing more. We are unwilling to believe in the existence of unprovoked malice, envy, and all uncharitableness. Ignorance is sufficient, we think, to account for much which bears the appearance of these vices. Ignorance of the laws of courtesy and kindness; ignorance of when they are violated. We are inclined to agree with Pope, that—

"Want of decency is want of sense."

Whatever may be the causes, however, from which acerbities spring, it is a most important thing to eliminate them as far as possible from scientific discussion. Even in their mildest form, they must have a most repressive influence on the freedom of debate. That discussion should be entirely unfettered, there can be no need to affirm or enforce; but there is an immense difference between liberty and licence. That errors should be pointed out, and misleading statements confuted, there can be no doubt; but that offensive language should be employed is surely unnecessary, and the misfortune is, that it too frequently happens, that as argument grows weak, phraseology becomes strong, and when the position cannot be destroyed, the person is assailed.

That this is a state of things to be deprecated cannot be disputed. The habit of pouncing upon, and "putting down" every accidental *non sequitor* or doubtful statement, except where important interests are at stake, is a most dangerous one in any individual, and often serves to keep silent others who, but for the indisposition to subject themselves to such treatment, might make important contributions to the common stock of knowledge. A case in point occurred only the other day at a photographic meeting. A gentleman whispered to his neighbour an important fact bearing on the subject of discussion.

"Why do you not get up and say so to the meeting?" was the reply.

"Oh, because I should probably have so and so down upon me immediately," was the rejoinder.

Where this tendency arises from inconsiderateness, combined with, perhaps, an over anxiety at all times for literal exactness and accuracy, we are sure that a very brief hint will suffice to correct it, and suggest the importance of some regard for the personal feelings of opponents, as well as for the elucidation of truth. Where it proceeds from ignorance, it rests with Photographic Societies and Photographic Journals to teach and enforce courtesy, by suppressing rudeness and personality in the meetings of the one, and excluding it from the pages of the other.

We cannot enter into any enlarged consideration of all the bearings of such a subject here; but we have been led into these brief remarks by the fact, that we have recently been compelled to omit from our pages letters containing important remarks on interesting subjects, simply because those remarks were expressed, in and accompanied by, an apparent spirit of personality and captiousness, to which, for the sake of free discussion, we are compelled to object. We have said an *apparent* spirit of personality and captiousness, because we believe, in some instances, the phraseology has simply proceeded from the inconsiderateness to which we have referred, aud not from any wish to offend. Unfortunately, where the motive is not apparent, the pain inflicted is not the less real.

Another motive which has induced us to make a few observations on this subject has arisen from the papers of Mr. Cramb, of Glasgow, on the silver meter controversy. Our readers have been made familiar with all the facts necessary for their guidance in this matter, and many of them have proved, practically, the value of the hydrometer for its purpose. Mr. Cramb has, in another angry article in a contemporary, returned to the question; but as a great part of his article consists of misstatements and abuse of ourselves, it were a bootless task, unpleasant to ourselves, and unprofitable to our readers, to follow him. Even had we been disposed to do so, we are somewhat disarmed at the outset by a statement that he is unable to find in his paper any just cause for the charges of rudeness which have been brought against him. Now, when a man can call the experiments performed before a scientific society to their entire satisfaction "complete befooling," and not know that he has been rude, there is but little to be said beyond an expression of commiseration of the crass obtuseness which must exist. It is bad to be rude; but it is simply unfortuuate to be so and not know it. Perhaps, even still, Mr. Cramb may be unwilling to take our word for it that he has been rude, and we must, therefore, refer him for confirmation to the courteous and sensible article of the editor of the journal in which his papers have appeared. As Mr. Cramb has referred to his national motto, apparently as a plea in mitigation of puuishment, we may commend to his attention some lines from his national poet:—

"Oh, wad some power the giftie gie us
To see oursels as ithers see us!
It wad frae mony a blunder free us,
And foolish notion."

ART-PHOTOGRAPHY.

An interesting paper on this subject was recently read before the Birmingham Society, by Mr. J. T. Brown, jun. The subject, as our readers know, possesses a peculiar interest to us, and, as we believe, to them; we shall, therefore, make a few extracts from Mr. Brown's paper, as it appears in the organ of the society, and add a few remarks of our own in passing.

An important part of this paper consists of an examination and comment upon Mr. Hughes's comprehensive epitome on the same subject, read some months ago at the South London Society,* and some exception is taken to an aphorism there announced, to the effect that "He is the highest artist who produces the greatest results with the smallest means." Now we have no desire to be the exponent of the exact meaning of Mr. Hughes's aphorism, but we apprehend that the idea just stated can scarcely be intended to be taken in an absolute or literal sense. It is the misfortune of all epigrammatic or aphoristic remarks that they convey, from their very terseness, too much or too little, and, if taken literally, require qualification or explanation. The remark just referred to, taken in a general sense, conveys a truth which few people will deny; but if pushed very literally, might be made to equally exalt the maker of [illegible] and with [illegible] the pictures traced with a red-hot poker on a panel of wood. Mr. Hughes was deprecating a tendency to regard a composition-photograph as worthy of especial attention or interest because it was produced from several negatives, and not because of its intrinsic excellence. Now we apprehend the truth is that neither paucity nor redundancy of appliances have any claim to be regarded in the estimate of a picture's excellence; they can only be admitted on the one hand in mitigation, or on the other in aggravation of censure, in case of failure or shortcoming. Perhaps a more comprehensive aphorism is that which defines the highest art as that which conceals the art, and leaves the spectator only possessed by the excellence of the work, without a thought to throw away upon the means by which it was produced.

The "smell of the lamp" can in no case be a recommendation; and in applying this idea to photography we may remark, that some of the best works of both Rejlander and Robinson leave the critics in doubt as to whether they are from a single negative or composition-photographs. We must, however, proceed with Mr. Brown's remarks. After a few introductory remarks on the aphorism of which we have first spoken, he proceeds:—

Before entering upon the question of Literal or Art-Photography, I will explain my views of art, which, summed up in a few words, consist of a "poetic" translation of the beauty and poetry of Nature, as rendered to the perception of the human mind through the medium of the sense of vision; and whether embodied upon canvas by the "artist" proper, by the mechanical aids at his command, or by the "artist-photographer" upon a chemically-prepared plate, with much less mechanical labour, through the means of his camera, yet both are dependent upon extraneous assistance—"mechanical"—whether manipulatory or otherwise.

If we take the whole scope of modern painting, and apply Mr. Hughes's test, we shall be compelled to award the palm of greatest excellence to Turner and David Cox, as in their works they have achieved stupendous results with an outlay of mechanical means marvellously small; while the followers of the pre-Raphaelite school—who have, I believe, by a strict and minute attention to the productions of photography, tended in a great degree to produce a higher interest in their profession than artists generally were possessed of before—would, from the extensive manipulation upon their pictures, be degraded to the lowest position. This would obviously be unfair. While I cannot but admit the productions of Turner or Cox to be the result of a more intimate knowledge of the mechanical means at their command, combined with an aptitude for converting that knowledge to its proper and natural use, I cannot condemn the fact that the study required by the observer to fully comprehend the subject-matter of the picture more than compensates for the extra labour or outlay of "mechanical" means they would have been required to render [illegible] more clearly apparent. In the pre-Raphaelite school the opposite principle has been adopted, and I believe we may not look upon the wonderful manipulation of most of that class of paintings without regretting how so much valuable time has been wasted by the artist that might have been turned to better account. In this particular photography will ultimately take the place of painting.

I have here a stereograph of a bit of scenery, "Trees and [illegible] Foliage." [illegible] would not have [illegible] a year beneath his pencil, though the time required to perfect it by the means at the artist's disposal, a finished picture of this bit of nature would have cost [illegible]. But the artist-photographer, provided with his camera and prepared plate, may produce in a few seconds, what to the painter would be a labour of months. And how much more faithfully! Colour only would be wanting; and in this the most important item, photography is at fault. While we can render the [illegible] aspect of nature—and the artist-photographer must not [illegible] to his [illegible] the use of the pencil is [illegible] to us, [illegible] the effects of photography [illegible]—still I am not without hope that we may, by a more careful analysis of the photographic power of colour, chemically applied, remove this difficulty, and place photography in a still higher position than it has yet aspired to.

I have also a set of stereographs, "Views upon the Avon," taken during the recent frost by one of our members, Mr. [illegible], which, although literal photography only in its lowest form, still shows that the appreciative powers of the artist have been employed, not only in the selection of the views themselves, but in the application of the art to copy the representation of nature therein displayed, as a memento of a scene which, for poetical beauty, has seldom been equalled. They also exhibit the superior powers of the artist-photographer over the artist. Had the latter wished to depict the sublimity of the scene, he would have utterly failed from the amount of time required to perfect—even were such perfection possible in human hands—a transcript of the view before him. But the former, by a simple movement of the cap of the lens, so as to expose for a few seconds his prepared film to the photogenic influence, receives an impression perfect in all its details, and still more perfect when viewed stereoscopically.

We must here interpose a remark. Mr. Brown refers to these views on the Avon, during the frost, which form a memento of a scene which for poetical beauty has seldom been equalled, as "literal photography in its lowest form." Surely he has entirely misunderstood the whole scope of Mr. Hughes's definition of literal or mechanical photography, when he applies it to the pictures he describes. In describing art-photography, Mr. Hughes observes, "In landscapes, the artist may select the period of the year, the condition of the weather, time of the day, point of sight (or view), length of exposure, &c., as artistical agencies in modifying his picture." In these winter scenes on the Avon all these conditions of art-photography, according to Mr. Hughes's definition, have been fulfilled. Mr. Brown himself adds:—

I am, therefore, disposed to class these productions among those of art-photography; but would, with all deference, throw out the hint, not only in the instance in this but in other cases, that where the poetical sublimity of Nature is aimed at, it would be well to dispense with the introduction of figures, which generally appear to be posed for that particular operation, and, to the educated eye of the artist, mar the effect.

Mr. Brown then proceeds to speak of the legitimacy of producing skies in photographs by the use of two negatives. He says:—

I maintain—and I think justly—that the artist-photographer, having met with a scene, and a sky which, in his judgment, is suited to that scene, [illegible] would be fully justified in [illegible] the cloud or sky, as it might be, to the plate and the landscape [illegible]. The [illegible] beauties of the one might be preserved intact, and a better opportunity would be afforded to obtain the [illegible] of the [illegible]

* See Photographic News, page [illegible] of the present volume.

He adds further:—

Again, Mr. Hughes cannot undertake to say that the natural sky is at all times that best suited to the picture. From some peculiarity of tone in the distance, the foreground, or the principal object in the view operating upon the chemically-prepared film in a manner far differently to the photographic effect upon the visual organ of the artist, a want of harmony would be produced; and, unless the artist-photographer has been educated to a fine appreciation of the photogenic effect of colour upon the chemicals he is generally in the habit of using, it is almost impossible, unless in rare instances, for him to produce upon a single plate the natural harmony of the scene.

The position maintained by Mr. Brown is that assumed by Mr. Fry. The same privileges are claimed for the photographer which are accorded to the painter. The latter, in painting a landscape, sees, during the progress of the work, the same scene of hill and dale, wood and water, frowning rock or grassy slopes, under a variety of aspects of light and shadow; a hundred fantastic clouds flit over it while he paints: all of these he cannot paint, but he selects and combines these effects so that whilst unity, harmony, and truth are not violated, a picturesque whole is secured. Can the photographer do this? Success is here, as in many other things, the touchstone of legitimacy. Mr. Hughes says in answer to the question, can we do this? "Let us hope we can. Let us try; but bear in mind, mere printing clouds into landscapes is not making perfect photographs. A fine photograph of clouds and sky is one of the most beautiful we can depict; but to join it on to a landscape without having a most tender regard for the nature of the subject, instead of raising the photographer to the rank of an artist, will only degrade him to the level of a mechanical printer." Mr. Hughes maintains that the highest claim of photography consists in its inexorable truth, and that composition-printing or "patchwork" tends to destroy that truth. In incompetent hands assuredly it does so; in the hands of the true and cultivated artist we think as assuredly it does not. But as mere "patchwork" is very simple and easy, it is as likely to fall into incompetent hands, or more so, than into the hands of the true artist, we think, there is indeed important need of an indignant protest against the idea that a print from many negatives necessarily constitutes an art-photograph. It is quite certain, that the true artist will not be likely to work with complex means, when simple ones will avail. What is required amongst photographers is an intelligent apprehension of the end to be attained, and of the simplest means to that end. In other words, more art education, more art culture to apprehend the object to be attained, more complete familiarity with all the powers and appliances of photography to compass the object desired. On this subject Mr. Brown observes:—

But, not only does the art of photography require further culture—whether in its artistic, chemical, or mechanical departments—we must, to render photography an art, educate our operators to that profession. A photographer may take a portrait or a view which shall exhibit a large amount of artistic feeling on his part; but if he had received an artistic education—if he had studied the harmonies of nature apart from photography—I maintain, with Reynolds and others, that he would not produce a picture wanting in artistic feeling. But, while he applies all his energies to art, he must not forget science. However artistic a man may be, he will often be foiled by apparent failures which might have been overcome had he been "up" in his chemistry or optics.

In other words, to secure the highest success, the cultivation of the photographer must be complete as a whole, in every branch of the Art and Science of Photography.

THE TANNIN PROCESS.

BY MAJOR RUSSELL.

Having experimented a great deal with the tannin process ever since I first thought of trying it, about nine months ago, I think I can throw some light on the means of avoiding the difficulties mentioned in your last number as attending its manipulation.

In the first place, my experience leads me to prefer a new collodion, giving a rather horny film, to an old and powdery sample. Every kind of collodion I have tried, old or new, thick or thin, would give good results with proper exposure, but the new is much more sensitive than the old; its use in my hands is attended with less mechanical difficulties, and the film, when dried, is much stronger and less liable to injury in printing. In fact, the suitability of a new collodion to this process is one of the greatest advantages it offers. For some purposes it may be desirable to keep the collodion a little time after iodizing, or to mix a little old with it, but it is better that the film should not be rotten or powdery.

The good effect of a bromide in the collodion is very marked in this process; both sensitiveness and facility of development are much increased by its use, and it renders less silver necessary to obtain sufficient density. The hardness of the negatives obtained from simply iodized collodion, results from under exposure, plates so prepared being very insensitive. The bromide should be used in much larger proportion than is usual; a course of experiments carefully conducted for the purpose seems to indicate that two grains of bromide to three grains of iodide is about the best proportion. Bromide of cadmium is to be preferred, on account of its great solubility in absolute alcohol.

I cannot imagine the cause of stains, unless it be insufficient washing of the plate to remove the nitrate, for in hundreds of trials, under all sorts of treatment, I have never seen anything approaching to a stain, except once, when the plates were, for experiment, slightly washed in distilled water. My practice is to put the plates, as soon as excited, into a dish of distilled water, removing them to a second dish of the same one by one when the first is full, placing fresh ones in their place in the first dish; when the second dish is full the plates are removed in the same manner into a dish of common water. Whilst each plate is in the exciting bath, after the first two dishes are full, one is removed from the second to the third dish, and another from the first to the second, so that no time is lost. Twelve plates may thus be easily excited and washed in an hour. The use of the distilled water is to remove most of the nitrate, and so prevent the violent decomposition and consequent adhesion of insoluble salts of silver to the film. The plates should not be less than a quarter of an hour in common water, half an hour is safer, and they may remain there much longer, if convenient, without any injury. I can detect no difference whatever between the quality of plates prepared in this way and of others soaked in strong salt and water, provided the salt be thoroughly washed out. If the dish of common water contains many plates, as soon as it is full the last placed in it will be ready to be coated with tannin solution. The surface of each plate should then be rinsed with distilled water, the back wiped dry, and the plate placed on a levelling stand, and the solution poured on and off once or twice; it should then be left covered with the solution whilst two more are treated in the same manner and left on two other levelling stands; the first will then be ready to be reared on one corner on filtering paper to dry, and another may take its place, and so on in succession till all are finished. It is not necessary to dry by artificial heat, but if this is done, the plates should not be exposed to the light of even a dull fire, as they are easily affected in this way.

With regard to the mechanical difficulty, my practice has usually been to coat the glass with gelatine; this entirely prevents all blistering or loosening of the film during development and fixing, unless the collodion be very unusually thick. If this plan be followed, it is as well to use fresh hypo, to which has been added a little tannin solution, so the film may retain no more of blistering after fixing, especially if the collodion be thick, or old and powdery. The use of the gelatine coating involves very little additional trouble, if properly and systematically done. The plates need not be cleaned with quite so much care as usual, and a large number may be coated with gelatine in a very short time, and stored, when well dried, in a tin box with paper between the extreme ends to prevent contact. In this state they may be kept any length of time in a dry room, and are ready for use on polishing the surface for a few seconds with a dry cotton-velvet rubber. Gelatine used in this way does not appear to injure the bath, at any rate for this process.

The whole preparation involves much less trouble than the collodio-albumen, even when the gelatine is used, but this is by no means necessary if the following precautions be attended to: either before or after exposure, the extreme edges of the plate should be varnished with a small brush and spirit varnish, which should be rather thick, to avoid risk of splashing on the surface. To develope, the plate should be placed on a levelling stand, and a little distilled water poured on it and spread over the surface with a perfectly clean glass rod, taking care not to touch the film except at the edges. On the application of the water the film expands so strongly that it is driven up in ridges all over the plate. If the development be commenced immediately, there is risk of breaking the film, especially if the collodion be old and rotton, besides which, the developer accumulating under the ridges will show in fine dark lines in the negative. If, on the other hand, the water be allowed to remain when spread over the plate for ten or fifteen minutes all will go well, in that time the film will have contracted again sufficiently to remove the wrinkles, and the contraction will continue during development, so that it usually lies quite flat by the time it is finished, and, contrary to what occurs in some dry processes, the film will adhere again to the glass perfectly.

I cannot yet say with certainty of what strength the tannin solution should be, but it is not of much consequence; ten grains to the ounce is quite enough to give very good results, and I have used it as strong as thirty grains; there are some advantages, and some disadvantages in using it so strong. Gallic or pyrogallic acid may be used to develop, the former requiring a longer exposure and giving a greenish colour, but both should not be used on the same plate, either mixed or one after the other, as this treatment is apt to cause red discoloration in the transparent parts of the negative near the sky, especially when a strong solution of tannin has been used.

The method of development published by Mr. Hardwich gives great advantages with dry plates;* not only can a large quantity of silver be used if necessary, without causing turbidity, but, in the case of an under-exposed negative, if a small quantity of silver be used, the half-tones come out much better, on account of the little acid present, than when the common plan is adopted. I think it better to make the pyrogallic solution rather stronger than recommended by Mr. Hardwich, 96 grains to the ounce of anhydrous alcohol, with a few drops of ether. The bottle which contains this solution must of course be stopped well; it will keep perfectly for six months, which is as long as I have tried it. The acid silver I prefer of half the strength mentioned by Mr. Hardwich. One drop of this is quite sufficient to bring out all the details faintly in six stereoscopic plates. The best way to use these solutions is, I think, to mix one drop of the silver solution and two drops of the pyrogallic solution in enough water to cover the plate; this will bring out the impression slowly, and will show in a few minutes what treatment is required, and more of the solution can be added, as may seem to be required: the more done it appears, the more silver should be added; the less done the more pyrogallic. This treatment gives great latitude in the exposure, if two plates are exposed, one twice as long as the other; with the same light and subject, it is easy to make the longer-exposed one appear less done than the other.

I have not yet tried the keeping properties to any extent, but have kept the plates a month before exposure, and six weeks more before development without any deterioration. Should a slight dulness appear on parts of the sensitive plate, from insoluble salts of silver, it may be removed by rubbing the surface when quite dry, with clean cotton wool, and dust may be removed in the same manner before putting the plate in the slide.

* Mr. Hardwich recommends the use of the following developing formulæ in this process: a solution of 72 grains of pyrogallic acid in one ounce of alcohol, which will keep good for months; 30 minims of this is added to three ounces of distilled water. This is the developing solution. Another solution of 20 grains of nitrate of silver and 20 grains of citric acid in one ounce of distilled water. From 10 to 20 minims of this are added to three drachms of the developing solution before applying it to the plate. If the plate appear under-exposed, the quantity of pyrogallic solution is to be increased and strengthened; if the plate appear over-exposed, then more of the citro-nitrate solution is to be added to give vigour to the otherwise feeble image.—Ed.]

THE LIME LIGHT.

Preparation of the Gases.

For the benefit of the uninitiated, I will endeavour to describe the method of making the gases, on a small scale, to produce the lime light.

When either gas is made upon a large scale, if I may so express it, several very different processes are used; but in these cases large furnaces and retorts are required, similar to the present gas-works for producing the carburetted hydrogen. For instance, oxygen is made from manganese, and other substances, which require nearly a white heat, and all these methods are more or less expensive, so much so, indeed, that though the production of cheap oxygen has long been a great desideratum, the apparent impossibility of ever procuring it in an inexpensive manner, has deterred practical chemists from investigating the matter. It is truly said, that the age of invention is in its infancy, and it is curious to look back upon the days when the producer of the first gas-light was thought a wizard, and the first steam-engine something awful to contemplate—yet with what different ideas we see these things now.

But to return to our subject—I may observe, that at last cheap oxygen has been discovered, and the residue, after its production, is twenty-two times the value of the original cost of the material used. Hydrogen may be obtained sufficiently pure by several methods. One is by passing superheated steam through iron borings. Another by passing superheated steam through coke. Both these methods require steam boilers, furnaces, iron retorts, &c.; and the hydrogen so produced costs only about eighteen-pence for a thousand cubic feet.

The simple methods I would recommend the amateur to adopt, are as follows:—In the first place, procure two wedge-shaped bags of the size required; they must be well and strongly made in order to withstand the heavy pressure they will have to bear. This pressure is calculated upon the area of the surface of the bag. For example—a bag measuring 2 feet each way will have an area of 4 square feet, or 576 square inches; and if the bag is 1 foot high at the larger end, multiply 576 by 12 (the number of inches) and the result will be 6,912, the half of this (the bag being wedge-shaped) will give the contents of the bag in cubic inches, viz., 3,456. It must be remembered, however, that the pressure upon the bag is not regulated by the *contents* of the bag, but by the area of its surface.

The pressure found to produce the best effect (and for photographic purposes this is what must be our aim) is about 3 ounces for each square inch of surface, or about a hundredweight for every four square feet of surface.

The pressure, as used in ordinary gas-works, is indicated by *inches of water*, calculated upon the fact that a column of water an inch square and 34 feet high weighs 15 pounds.

It will be necessary to have a large aperture to the jet used for photographic purposes, one admitting of the consumption of about 6 cubic feet of the combined gases per hour, *i. e.* 4 feet of oxygen and 2 feet of pure hydrogen.

As regards the use of carburetted hydrogen instead of pure hydrogen, I have previously spoken. This consumption of gas will guide the amateur as to the requisite size of the bags. I would recommend both to be made of equal size, and it is absolutely necessary that each should have the *same* amount of pressure upon it. It is advisable, perhaps, to state that the pressure must be put upon the bags *before* lighting the lamp, and that this pressure must not, on any account, be removed until the light is put out, or the consequences may probably be an explosion. The gas-bags are placed between two boards called pressure boards, and may be described as somewhat resembling the cover of a book, they are strongly hinged together at one end, and a kind of shelf is made at the opposite end of the upper board to hold the weights and prevent them sliding off when it is raised by the gas-bag. Midway between the hinges a portion of the boards is cut away to allow the stopcock to protrude.

Now, as regards the manufacture of the gases:—Procure a pneumatic trough and a Wolfe's bottle, which has three necks. Through one neck, pass a glass funnel, and let it reach to the bottom of the bottle. This is for pouring in the mixture of sulphuric acid (one part) and water (six parts); it also acts as a safety valve and indicator, for by it you can judge if the gas is making more quickly than it can escape into the receiver and thence into the gas-bag, with which of course the receiver is connected in the ordinary way. The second, or centre neck, is used for the admission of the pieces of zinc into the bottle, and the third neck has a bent tube passing through a cork fitted into it, the tube does not reach further into the bottle than the cork does. An india-rubber tube is passed over this glass tube and this connects it with another bent glass tube passing through the water in the pneumatic trough, and so under the glass receiver for collecting the gas as it escapes. By passing through the water it is cooled and purified. The receiver is simply a glass bell-shaped vessel with a tube fitted into the top of it, over which is passed the india-rubber tube connected with the gas-bag. All the corks and fittings must be properly luted with a paste made of linseed meal and water. The glass tubes should be half an inch diameter, and the india-rubber tubes three-eighths the diameter. Zinc is procurable at 1½d. or 2d. per pound, and sulphuric acid at the same price. Great heat is evolved as the gas is generated. The diluted acid must be poured in gradually, and more added by degrees when the gas begins to come over slowly. When the bottle is nearly full of the diluted acid, and gas has ceased to come over, it will be found more expeditious to disconnect it, and pour it away, instead of adding more of the diluted acid to it. The bottle must always contain a superabundance of zinc. When not in use all the liquid must be emptied out of it to save the corrosion of the zinc. This liquid is sulphate of zinc in solution, which by evaporation may be saved, it being of some value. When pure it is worth fourpence an ounce, but when produced as above mentioned, it contains a compound of arsenic. Its value is not sufficiently great to make it worth the while of any amateur troubling himself about it.

To make the oxygen, procure a copper retort of a spherical or other shape, having a plug fitting into it, to admit a mixture of three parts of chlorate of potash, at a shilling a pound, and one part of black oxide of manganese, at three-halfpence a pound; they must be perfectly dry and well mixed together. The plug is then fitted into the retort by a blow with a hammer. In the centre of the plug is a screwed aperture for a bent copper tube, about four feet long, to this an india-rubber tube is fixed (as before described). the other end of which is connected with a glass tube, which passes to the bottom of a glass bottle containing water, through which the gas rises as it is given off, and thus cools before entering the gas bag. The same cork, through which the last-mentioned glass tube passes, may also hold a second glass tube passing only to the bottom of the cork (so to speak), and bending over at a right angle above the cork, to this end of it the india-rubber tube of the oxygen bag is attached. The copper retort, when charged, is put upon a slow fire, or over an Argand lamp.

Previous to filling the bags, all the air must be forced out of them by rolling them or otherwise.

It is advisable to mark the bags, and keep each for its respective gas, and on all occasions to be careful that the gases are not allowed to mix before they reach the brass wire-gauze near the point of ignition.

To test the oxygen bag, should any leakage be suspected when the pressure is on, light a piece of brown paper, blow it out, and bring the smouldering portion near the suspected leakage, if oxygen escapes, the paper will burst into flame. There is no fear of explosion with the oxygen bag, unless hydrogen has been forced over into it, which is sure to be the case if the stopcocks are opened before the pressure is put on the bags, and the weights put on the hydrogen bag first and the oxygen bag afterwards. Have everything correct and ready before the stopcocks are touched.

It is well to mention, that it is not safe to take a light into close proximity with the hydrogen bag; no one can be too careful in the management of explosive gases.

When the contents of the copper retort cease to give over any more gas, let the retort cool, and then pour water into it. The mixture, although it will have been found to have caked together, will, by this means, be quickly loosened, and may then be poured away, and the retort put a moment on the fire again to dry, and then put away till required again.

Half a pound of the oxygen mixture, as above described, will produce two cubic feet of gas. S. S. B.

Scientific Gossip.

MR. NASMYTH has recently added some important facts to our knowledge of the physical constitution of the sun. He has discovered that its entire surface is composed of objects of the shape of a willow leaf. These objects average about 1,000 miles in length and 100 in breadth, and cross each other in all directions, forming a net-work. The thickness of this does not appear to be very great, as through the interstices the dark or penumbral stratum is seen, and it is this which gives to the sun that peculiar mottled appearance so familiar to observers. These willow-leaf-shaped objects are best seen at the edges of a solar spot, where they appear luminous on a dark ground, and also compose the bridges which are formed across a spot when it is mending up. The only approach to symmetrical arrangement is in the filaments bordering the spot, and those composing the penumbra, which appears to be a true secondary stratum of the sun's luminous atmosphere. Here these bodies show a tendency to a radical arrangement. Although carefully watched for, no trace of a spiral or vortical arrangement has been observed in these filaments, thus setting aside the likelihood of any whirlwind-like action being an agent in the formation of the spots, as has been conjectured to be the case. Mr. Nasmyth states that he does not feel warranted at present in hazarding any conjectures as to the nature and functions of these remarkable willow-leaf-shaped objects, but intends pursuing the investigation of the subject this summer, and hopes to lay the results before the British Association during their meeting in Manchester. In illustration of these curious facts we have had the pleasure of inspecting three beautiful drawings, one representing one of the willow-leaf-shaped objects; another the luminous surface of the sun as being entirely composed of these objects; and a third, a large drawing of a solar spot as seen on the 20th of July, 1860, exhibiting the surface of the sun as composed of these objects, also the penumbra and the bridges across the dark portion of the spot on which the exact shapes of these objects were to be seen most clearly. The image of the sun was examined by Mr. Nasmyth with a mirror of plane glass set at an angle of 45 degrees; nearly the whole of the light and heat of the sun passed through the glass, and the rays used were those only reflected from its surface. It would be a very important step for some photographer to attempt to photograph one of these objects. An enormous amplification would undoubtedly be requisite, and very perfectly ground lenses and reflector; but the usual difficulty, want of light, would not introduce any of its usual obstacles in the way of obtaining good photographic representations of these wonderful "willow leaves." It is a maxim with us, as it ought to be with all photographers, that what we can see we can photograph. These have been seen by Mr. Nasmyth, and therefore their photographic fixation should not be far distant.

Now that the beautiful phenomena of the spectra of artificial lights are attracting so much attention, it is with pleasure that our readers will learn that most of the fundamental phenomena upon which the researches of Bunsen and others are based, were originally observed and described by English scientific men. To Fox Talbot we owe very much of our knowledge of the spectra of artificial flames, and Professor Wheatstone has also experimented assiduously in this branch of physical optics. One of the most important papers on this subject was read some years ago by the Professor, at a meeting of the British Association. It was, however, never published in full, and consequently received little attention, except from those who were fortunate enough to be present when it was read. Having lately had an opportunity of seeing the complete paper, (which will shortly be published in full in the *Chemical News)* we were so struck with the beauty and originality of the experiments there described, that we hasten to lay a full abstract of it before our readers, feeling assured that the subject is one in which they cannot fail to take an interest.

The title of Professor Wheatstone's paper is "On the Prismatic Decomposition of Electrical Light," and the following is an abstract of the principal results stated in it:—"1. The spectrum of the electro-magnetic spark taken from mercury consists of seven definite rays, only separated by dark intervals from each other; these visible rays are two orange lines close together, a bright green line, two bluish-green lines near each other, a very bright purple line, and, lastly, a violet line. The observations were made with a telescope provided with a measuring apparatus; and to ensure the appearance of the spark invariably in the same place, an appropriate modification of the electro-magnet was employed. 2. The spark taken in the same manner from zinc, cadmium, tin, bismuth, and lead, in the melted state, gives similar results; but the number, position, and colours of the lines vary in each case; the appearances are so different, that by this mode of examination the metals may be readily distinguished from each other. A table accompanies the paper, showing the position and colour of the lines in the various metals used. The spectra of zinc and cadmium are characterised by the presence of a red line in each, which occurs in neither of the other metals. 3. When the spark of a voltaic pile is taken from the same metals, still in the melted state, precisely the same appearances are presented. 4. The voltaic spark from mercury was taken successively in the ordinary vacuum of the air-pump, in the Torricellian vacuum, in carbonic acid gas, &c., and the same results were obtained as when the experiment was performed in the air or in oxygen gas. The light, therefore, does not arise from the combustion of the metal. Professor Wheatstone also examined by the prism the light which accompanies the ordinary combustion of the metals in oxygen gas and by other means, and found the appearances totally dissimilar to the above. 5. Fraunhofer having found that the ordinary electric spark examined by a prism presented a spectrum crossed by numerous bright lines, Professor Wheatstone examined the phenomena in different metals, and found that these bright lines differ in number and position in every different metal employed. When the spark is taken between balls of dissimilar metals, the lines appertaining to both are simultaneously seen. 6. The peculiar phenomena observed in the voltaic spark taken between different metallic wires connected with a powerful battery were then described, and the paper concluded with a review of the various theories which have been advanced to explain the origin of electric light. Professor Wheatstone infers from his researches, that electric light results from the volatilization and ignition (not combustion) of the ponderable matter of the conductor itself; a conclusion closely resembling that arrived at by Fusinieri from his experiments on the transport of ponderable matter in electric discharges.

In a recent number of the Photographic News we gave an account of some remarkable experiments tried, and results obtained, upon a spring in Florida, from which the inference was drawn that water was almost perfectly transparent. These observations were necessarily rough, being tried at the margin of the spring, with cards, &c. Dr. Tyndall has now shown, by a series of beautiful and conclusive experiments, that water has a decided colour—that even in small thicknesses it is not the colourless substance it is usually imagined to be. When seen through a glass full of the liquid, of course it appears without colour, but if looked at through a stratum of fifteen feet its colour is very evident. The following is Dr. Tyndall's arrangement of the experiment for showing this to a large audience. A tin tube, fifteen feet long and about three inches in diameter, is placed horizontally on a stand, and half filled with water. The tube is closed by plate glass at each end, and a beam of electric light is thrown through it from the other end. By this means an image of the contents of the tube is projected on a white screen. The tube being about half filled with water, and the image upon the screen being inverted by the lens, the upper air space in the tube is seen in the lower part of the image, which is quite colourless; whilst the upper portion, illuminated by the rays which pass through the stratum of water, is of a greenish blue colour. The colour varies from a pure green up to a blue, according to the purity or otherwise, of the water. Thus it is evident that the colour of water is very appreciable, for in a stratum of fifteen feet a very considerable amount is exhibited, and thus there is no difficulty in comprehending the fact, that in looking through a deeper stratum, such as is seen in the Swiss lakes, and in the waters which we have around our own shores, this colour of water makes itself very perceptible.

AN APPEAL FOR THE PRACTICAL IN ARTISTIC PHOTOGRAPHY.

BY A. H. WALL.*

The new art has *not* reached its limits, and we societies know very well that there *is* something further to be accomplished. There is indeed *much* to be done, and that in every branch of the art. We require, and are grateful for, the labours of our opticians, our chemists, our mechanics, and our operators; but above all it is necessary that our artists should be active, inasmuch as theirs, the highest and most important branch of all, has been most neglected. We don't want abstruse theories from any of them. Such things will do well enough when we have done our more necessary work; but now every paper we read, every experiment we undertake, and every discussion in which we take part should have some practical or suggestive value.

Photographers too frequently look with an eye of jealousy upon the artist, because, regarding all art as purely imitative, they can't conceive a work of the hand and eye as more perfect than the results of a process which they regard as infallible. Hence it was that when such artists as Sir Charles Eastlake, Sir William Newton, Rejlander, Lake Price, and others came amongst photographers, mutual misunderstandings soon estranged and separated them. If an artist, venturing out of his native element into that of science made a false step, some eagle-eyed scientific photographer swooped down upon and held him up to ridicule and laughter; and if a scientific photographer, rashly invading the domains of art, advocated some glaring artistic blunder, or piece of evil taste, up rose the representative of the palette, and down went the gauntlet once again.

* Continued from p 125

Now, however, a change is taking place. We know that our lenses require artistic management, that our knowledge of pictorial science must give our chemical knowledge its real value, and that mechanical perfection helps us to artistic results only when we have the power of using such judiciously. The hand may be there, but it wants the head to guide it; the body may exist, but it wants the soul to animate it. Let us, therefore, cultivate, not this or that branch of photography, but *all* its branches. Let us aim to bring together and unite harmoniously every element of our art's success, so that our societies may be formed of artists, opticians, chemists, mechanics, and operators; bound together by their common interest in the art they love, and working out *practically* the grand problem of its ultimate perfection, undisturbed by petty jealousies, or idle controversies, and working, not with words only, but with words and *works*.

To embody the progress which may thus arise we shall look to our societies' photographic exhibitions, which will thus become the medium of communication between us and the public, and fight our art's battle against adverse critics. My sole object in this paper is to advocate the practical. To this end we need our best efforts. We must not be content with bringing this process out, and that modification forward; but rather direct our efforts towards the perfection of existing processes. Novelty has great attractions, for he who brings forward the veriest trifle of a discovery is more lauded and honoured than the steady plodder who conducts us slowly and surely onwards to perfection. Here then we want a little reform. Let the palm be given to the practically useful; the meed of honour to the doer of good things, rather than to the suggestor of idle or unprofitable experiments.

To simplify and render more certain every step in the practice of photography is one of our tasks; and here I cannot do better than quote a writer in a recent number of the *London Review*, who, writing upon "Photography as a Fine Art," says, "when its processes become more manageable, as much so, in fact, as the crayon in the hands of the painter, then will photography approach still nearer to a high place among the fine arts; for, inasmuch, as being less dependent on manipulation there will be more room for the exercise and display of the artistic faculty. Every year brings us nigher to this desired consummation," and if united by a common love of our glorious art, we all work together, as our various acquirements and experiences dictate, each labouring to perfect that element, branch, or process with which he is best acquainted, we cannot fail so to improve the character of our photographic exhibitions that the stigma of the mechanical will be laughed to scorn both by photographers and the public.

While speaking of exhibitions I may perhaps be permitted to express my very high appreciation of a system adopted by the Photographic Society of Scotland, that of awarding medals as prizes for the best photographs exhibited. The value of such prizes will of course depend upon the real merit of the qualities for which they are awarded, inasmuch as it is of course the honour implied rather than the intrinsic value of the medal, which renders them so desirable. Of course I need not, therefore, add, that while the judges, *being thoroughly able and competent gentlemen*, should be guided by the success achieved: they should rather reserve such prizes altogether than award them for acquirements or specimens of an inferior description. The greatest success of the highest nature should carry off the prize. The simple medal then, represents more honour, and is, consequently, more eagerly desired and more earnestly sought; thus best serving the high purpose for which they were intended.

In concluding these few suggestive remarks I again take up my text, and repeat that for real progress, both upwards and onwards, we must look to our practical members. Whatever we do let us be practical; we may sometimes feel when discussing a piece of mechanism, or some point of simple manipulation, that such an employment has but little dignity in comparison with the high flights we have taken into the loftiest heaven of science; but our art is a peculiar one, embracing, as I have shown in my opening remarks, the noblest and the meanest, the loftiest and the lowliest, and not infrequently the largest and most important sucesses are due to the perfection of some trivial piece of mechanical ingenuity, or some apparently unimportant improvement in manipulation. Therefore, whatever the nature of our work, let it be earnest and practical, whether it be claimed by mechanics, science, or art.

Gentlemen,—I will not now detain you any longer; already, perhaps, I have exhausted your patience, but I could not resist the opportunity of placing before so influential a society, for consideration and discussion, the few preceding suggestions. If in so doing I have made a mistake, I can only ask, what I think in consideration of my earnestness you will kindly grant, viz., a full pardon.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.

We make the following interesting extracts regarding the Scottish Exhibition from the various criticisms in the Edinburgh newspaper press. The *Scotsman*, in a second notice, remarks—

"The perfection to which sun printing has attained within so very short a time is scarcely less wonderful than its origin. Being one of the latest, though not the least remarkable, of modern discoveries, many who were present at its birth still survive to witness its ripened power and rejoice in its triumphant success. The time has been, however, and that not long ago, when its merits in an artistic sense were not so conspicuous as now. The discovery of Talbot gave a new impulse to the art, and within the last few years both the chemical manipulation and construction of the instruments employed have been so much improved as to render the process almost perfect. But mechanical means alone, however perfect, are not sufficient to form a good photographer. He must, in addition, possess artistic taste and knowledge—a capacity for arrangement and composition, to enable him to place his model in the position best adapted for displaying its natural advantages, and by a skilful distribution of the chiaroscuro and appropriate use of accessories, to give it all the advantages of contrast and effect of which the subject may be susceptible. It is the possession of these qualifications which gives to the photographer the title to be called an artist. Without them, however dextrous in the use of mechanical means, he is a mere *caput mortuum*—a body without a soul. No better illustration of what has been stated could perhaps be found than in a brief reference to the art as it existed some years ago in comparison with its present state, as shown by the Exhibition now opened. Many will still recollect the hideous productions which used to be denominated portraits. If the model happened to be a clergyman or professional man, wearing a white neckerchief, what a contrast did the portrait present? The face usually of the hue of blacklead, rested upon a pillow of snow, presenting a considerable resemblance to a subject often treated by the old masters—'The Head of St. John on a Trencher.' And then, from the defective character of the instruments employed, the form was much of a piece with the colour—eyes front, nose profile, mouth awry, was the general formula of a head, and as for character or expression, such qualities were never even aimed at. It may, no doubt, be said that such abortive attempts exist even at present, but now they are the exception, formerly they were the rule, and those who produce such works now have no more right to be termed photographers than the dauber of a signpost has to be called an artist. In landscape, the results were equally unsatisfactory. These old things, however, have passed away, and photographic portraits in truth, spirit, and character, in all the main essentials of art, rival the best productions of this or any other age. The beautiful works of Claudet, Tunny, Moffat, &c., ay, even of the amateurs L'Amy and Mitchel Innes, in the present Exhibition, will amply bear out our statement, while the able and complete landscapes of Mudd, Maxwell Lyte, Vernon Heath, Annan, and many others, are not less satisfactory and delightful. Many we know have by its early specimens been repelled from the study of photography. To all such we would say, Go and see the present Exhibition, and if you have any music in your soul, it cannot fail to be called forth in tones of pleasure and satisfaction. To the lover of art, of whatever kind, we would also give a similar advice. Photography has been designated the handmaid of art; and if it be so, the present Exhibition may not inaptly be termed the vestibule to that of the Royal Scottish Academy just opened. Intending visitors to the latter should, therefore, lose no time in quickening their powers of observation, and increasing their capacity for enjoyment, by a study of the sun pictures, which afford a sure standard whereby to test, in many respects, the works of human genius. We may take this opportunity of stating that Mr. Robinson has assured us that his two beautiful photographs of a 'Holiday in the Wood,' and 'The Top of the Hill,' are both the productions of last season; and we are now satisfied that our recollection was at fault in stating that the former had been seen previously by us. It was another work by Mr. Robinson which ran in our mind and caused the mistake."

The *Caledonian Mercury* has the following remarks :—

"The picture which has received the greatest share of attention, is No. 65 in the catalogue, entitled 'A Holiday in the Wood,' the artist, who is likewise the exhibitor, being Mr. H. P. Robinson. It is the largest figure composition ever attempted in photography. A group of merry girls and boys are disporting themselves on a grass-knoll on the borders of a leafy grove. One is in eager pursuit of a butterfly; another crowns a companion with a wreath of summer flowers; a third laughs at the story or jest of one of the little group seated near in the long deep grass. Not one of the many figures represented has the slightest appearance of having sat for his or her portrait, and the grouping and arrangement are most artistic. The landscape is full of air and sunshine. The leaves and grass are instinct with rustling life, and the eye wanders with delight through the deep and transparent shadows of the grove, away to the distant gleams of the bright sky beyond.

"The Exhibition is particularly rich in studies of trees. No. 314, 'A Lane Scene' (collodion) is executed and exhibited by Mr. J. Dixon Piper, who contributes nine pictures, all worthy of high praise. The 'Lane Scene' is made of the simplest details—a few trees, through whose branches the bright sunshine falls on a woodland path leading to a picturesque field-gate. The alternate light and shade, besides the fidelity of their rendering, assist in giving a deep perspective to the back ground which peeps from behind the bars of the sun-flecked gate. No. 298, 'Study of Trees' (collodion), and No. 391, 'Chesnut Tree' (collodion), are by the same artist. The subjects are well chosen, and truthfully treated. The foliage of each of them is free from the woolly appearance sometimes seen in photographs of grass and trees. Each leaf is distinct, from the grass blades of the field up to those that

'Dance so light, and dance so high,
On the topmost bough that looks up to the sky.'

Perhaps the finest realisation of forest scenery in the Exhibition is No. 291, 'Pass of Killicrankie' (col. albumen), by Mr. James Mudd, who is the artist and exhibitor of eighteen pictures, all of which are certain to become public favourites. In the above picture is represented a dense forest of pines, in the centre of which is embowered a cottage which breaks up the monotony of the countless trees, whose tops rise and fall in graceful undulations, until lost to sight behind the downward slope of the pass.

"Mr. J. H. Morgan is artist and exhibitor of six pictures. No. 376, 'The Rising Mist,' (collodion) is a perfect gem. In front is an ancient bridgeway, across which the sunshine, streaming through the tree tops, falls in many patches of light. Beyond the bridge a clump of trees is dimly seen through the mist. Sometimes similar misty effects are the results of imperfect development, but minute examination will prove that this is the veritable presentment of a summer haze.

"Mr. Vernon Heath, the artist and exhibitor of fourteen pictures, is particularly happy in the pleasing tint which pertains to all his photographs. Of these we prefer the four pictures numbering from 56 to 59 (collodion); the first, a view 'On the Cornish Bank of the Tamar,' is our favourite. In one or two pictures the foreground is rather confused and misty, and the water—but what league of lens and sensitized plate ever could catch the limpid transparency of leaping stream or rolling river—is (for want of a better word) cottony.

"Mr. T. Annan is the artist and exhibitor of fifteen pictures. No. 276, 'Aberfoyle' (collodion), is one of the most charming photographs we remember ever to have seen. It is balanced with due regard to artistic rule, and is in keeping with the subject and the season. In the centre of the picture is the Clachan, consisting of two cottages, immortalised by Sir Walter Scott. The rude masonry of the one and the white plastered walls or the other are given with minute distinctness and without glare. A heather-covered brae slopes upwards to the right of the Clachan. A peat-cart is introduced midway this ascent, and its white shafts and wickey-fashioned sides carry up the light in a graceful line to the patch of fleecy cloud which overhangs the strath. Across the middle distance runs a long range of bosky hills, and behind rises 'broad Benlomond,' in solitary grandeur. Another of this artist's pictures, No. 280, 'Inversnaid Waterfall,' is, with the exception of want of sparkle in the foam, excellent; the lichened rocks and boulder stones, the unquiet pool beneath the cascade, and the calm water of the pool lower down, are true to nature. It is to be regretted that these pictures are not 'untouched' photographs.

"Dr. Walker, one of the Council of the Society, is the artist and exhibitor of two photographs, Nos. 304 and 305 (waxed paper), and twelve stereograms. Of the two pictures we prefer the latter, entitled 'On the Esk, Dalhousie.' This river, the most picturesque of Lothian waters, is a peculiar favourite of painters and photographers, and its shady, sunny nooks, long ridges of sand and rock, lazy pools and wooded banks, are characteristically rendered in Dr. Walker's picture. The tint is pleasing, and closely resembles that of Mr. Vernon Heath's best photographs. In strong contrast to the foregoing landscapes is Mr. Maxwell Lyte's, No. 296, 'Cirque de Gavarini' (collodion), a weird-like scene well fitted for the orgies of a Walpurgis revel. On either side of a deep gorge, through which rushes an impetuous torrent, rise frowning precipices, and above and behind the glaciered and snowy Alps. We experience a sensation of chill and terror looking on these inaccessible cliffs, crowned with perpetual winter and clothed with drizzling mist. All these features and effects are forcibly given in this picture. No. 28, 'The Falls of Terui,' photographed by Mr. R. M'Pherson, and exhibited by Mr. G. Thomson, is very bold in treatment; but the picture is marred by the sombre tint of the rocks, which gives the view the appearance of a cascade tumbling into a dark cavern. William Church, junr., contributes only one picture, No. 266, 'On the Gareloch.' Although the work of a non-professional, it is one of the best second-rate landscapes in the Exhibition. The shelving pebbly beach, laid bare by the tide, is extremely beautiful. The tone of the picture is however deficient in warmth, and the sun has been assisted in his 'cloud painting.'"

Proceedings of Societies.

Manchester Photographic Socuty.

The monthly meeting was held on Wednesday the 6th inst.—Joseph Sidebotham, Esq., in the chair.

After the election of some members, the presentation of some reproductions by Mr. Brothers, and some other routine business,

Mr. Sidebotham vacated the chair, and read a highly interesting paper on some of the causes of distortion in photographic portraits. We make an abstract of the paper as it appears in the organ of the society. After referring to the admitted varieties as likenesses, which different photographs of the same person often presented, and the unquestionable defects and distortion which often prevail, he proceeded:

Sir David Brewster and others maintain that the correct aperture with which to take a portrait should be a very small one—as small, if possible, as the pupil of the human eye; others contend that a lens, or combination, of large aperture should be adopted, not only as increasing the rapidity of action, but as also giving greater roundness and prominence to the portrait.

Let us examine portraits taken under both these conditions; and, first, that taken with the small aperture. You can find no positive fault with it; but there is a flatness about it, and you perceive at once that it is not satisfactory. It is in fact like looking at your friend's face with one eye, and to a person who is unfortunately furnished with but one, would no doubt be pronounced an admirable likeness. Look at portraits taken with a lens of large aperture. They have not the fault of being flat, but stand out extremely well. Still the features do not appear correct; there is evidently *distortion*, although we cannot exactly find out *where* it exists.

It would appear then, that neither the small aperture or the large one give accurate portraits; in fact neither looking at a friend with one eye, or looking at him with a number of eyes, arranged in a circle of three inches in diameter, would give us the same result as we have by looking at him with two eyes.

If we take a small cube, of an inch in diameter, and take a photograph of it, using a small aperture, or what is the same thing, look at it with one eye—we are able to place it so as to see three of its sides. If we use a large aperture lens, we can so place it as to take a picture showing five sides; but if we look at it with both eyes we can only see four sides.

Let us now see if this does not assist us in solving the problem. To depict the portrait on a flat surface as seen from a single point, the small aperture is no doubt correct. But we want a *likeness*. We do not care for the mathematical precision. We want a picture of our friend's features as they appear to us.

To take a portrait so as to give the likeness the same as we see with both eyes, we ought theoretically to use a diaphragm with two small openings, one at each margin of a three-inch lens, arranged horizontally like the eyes. In practice this does not answer, as the two apertures yield dissimilar pictures, which, although falling on each other, do not blend together to form one image. But we can produce a modification of this, which removes the difficulty, and it appears to me this is exactly what we require.

Mr. Sidebotham then stated that his own plan was to use a slit-like diaphragm, giving the extreme limits of the vision of each eye in a horizontal direction, and entirely cutting off what might be termed the *vertical* stereoscopic effect, which was the cause of so many unpleasing portraits. Thus getting the roundness of figure, as in the large lens portrait, reducing the amount of distortion to a minimum, this would obtain copies of their friends' faces, as they saw them, and produce perfect photographic portraits.

Mr. Sidebotham's paper was illustrated by diagrams and the exhibition of specimens.

Mr. Brothers was quite aware that distortion was frequently seen; but he believed that much depended upon the lens used, and he thought, if operators were careful in their choice, that most satisfactory portraits might be taken with a large aperture of the ordinary character.

Mr. Sidebotham remarked that the question of good and bad lenses did not bear upon his argument. In order to test his theory, any lens might he employed, and its capabilities ascertained with the ordinary stop, as compared with the arrangement he proposed. His argument was briefly this: that in taking a portrait with a small aperture the rotundity is lost, because the effect is that which we should get by viewing the object with one eye only. If a large aperture were used, then the rotundity was obtained; but distortion arose from the fact that a stereoscopic effect, in a vertical direction, exists. With his form of stop the picture was taken by an aperture corresponding to the arrangement by which they perceive the sitter.

Mr. Brothers doubted whether he should be able to work in his glass-room with so narrow an aperture as that recommended.

The Secretary said that Mr. Sidebotham's theory carried truth with its enunciation. It appeared to him to be one of those things that was simple enough when found out, but which everybody had been in search of until then without success. In reference to Mr. Brothers's remark that there would be a want of light, he observed that, to carry the principle out perfectly, the opening should of course be the diameter, in a vertical direction, of the pupil of the eye, and the length the distance of the eyes apart; but in practice these dimensions might probably be enlarged without any perceptible loss of truth.

After some further conversation the discussion was adjourned.

Mr. Noton then described a new plate-holder which he had invented.

After some further conversation on this subject, and an explanation from Mr. Hooper regarding a transaction in connection with the panoramic lens, the proceedings terminated.

Photographic Notes and Queries.

Stereo-Exchange Club.

Sir,—You would confer a favour upon myself and many others of your more recent subscribers by publishing the names of gentlemen desirous of exchanging stereograms. Might I suggest that you certify your intention of doing so on a particular day, and request that *a fair average print* be sent to you, for approval, by each person desirous of having his name inserted. The accompanying stereogram was taken under unfavourable circumstances, and was, in fact, only intended as an experiment, in order to test the powers of a pair of Ross's lenses, which I had just received.—I am, sir, yours, &c.,

Langerig Hall, March 18, 1861. C. F. B.

[As soon as we receive a sufficient number of names, we shall publish another list. Those of our readers who may be anxious to avail themselves of the advantages of this exchange, will please to forward their names and specimen prints.—Ed.]

Yellow Glass for Dark Rooms.

Dear Sir,—I notice in the Photographic News of to-day a letter respecting yellow glass, from which it appears there is some difficulty in procuring a thoroughly-suitable tint. As I have always manufactured my own, and found it completely satisfactory, I send you my plan, which may perhaps be useful to some other photographer. I dissolve 1 oz. of shell lac, 1 drm. of gum elemi, and 1½ oz. of powdered gamboge, in 6 oz. of vegetable naphtha; when the gums are quite dissolved, which will be in a day or two, decant the varnish off the dregs, and apply to the glass—quite dry and rather warmed—with a broad camel-hair tool. It will be dry in a few minutes, and may then have another coat, or more if requisite, to give the desired tint. This glass transmits a good softened yellow light, I believe quite non-actinic. There is also the advantage that the varnish can easily be applied to existing windows, lanterns, &c., if desirable.

Does "Hardwich's Manual" give the routine of the principal photographic processes—positive and negative collodion, printing, copying, &c.? I think it would be to their own advantage if he and other publishers were to ventilate their new editions in your advertising columns a little more freely. I have been looking out for a handbook bringing up processes to the present time; but till I saw your article on the "Tannin Process," I was not aware that one had recently come out.—I remain respectfully, J. J. Larriston.

The Abbey, Wigton, March 16, 1861.

["Hardwich's Manual" is a very complete epitome of most of the collodion processes.—Ed.]

Panoramic Photographs—Tannin Process.

Sir,—It may be useful to some of your readers to know of a means of taking small panoramic pictures, *i. e.*, double the length of a stereoscopic picture, without going to the expense of the panoramic apparatus.

I have taken a few upon stereoscopic dry plates, of which the enclosed is a specimen, by exposing first one view, say the right on the left half of the plate, then moving round the camera and taking the other half in a similar way.

If the two are made to meet accurately in the middle, there will be very little line visible in the print.

In order to view them to advantage, I have made the lenses of my stereoscope to slide out and reverse, so as to use them as an ordinary lens, or pair of lenses, for viewing these pictures. My stereoscope has a screen between the lenses and the picture, with two apertures in it through which to view stereographs, but hinged so as to shut down when using the instrument for single pictures.

It is astonishing how important the picture looks when viewed in this way, and how well it bears magnifying if taken from a sharp negative.

In order to shield myself from the attacks of artists on the one hand, and panoramic lens makers on the other, I beg to say that I am perfectly well aware that the laws of perspective are set at defiance in thus uniting two pictures, and, therefore, the subjects must be judiciously chosen.

In such subjects as the one sent I suppose no one could *see* that the perspective is incorrect, therefore the knowledge of its *being* so need not make one unhappy.

The picture is taken by the tannin process, which may be truly said to beat every other preservative, as far as my experience goes, and for the publication of which Mr. Hardwich deserves the thanks of the photographic world.—Yours obediently,

Cheltenham, March 15, 1861. G. S. Penny

P.S.—Some photographers having been once intoxicated with the gin and water preservative process, your teetotal photographic readers may be exhilarated by the information that their favourite beverage, which in the cup is allowed to "cheer but not inebriate," may with advantage be also served upon a plate.

I announce this discovery, lest any enthusiast might be induced to take out a patent for this new mode of "dishing-up."

Seriously—I have prepared a plate in all respects as for the tannin process, only substituting, as a preservative, a strong infusion of black tea. The plate was exposed under a negative to artificial light, and yielded a very good print, bearing in every respect a strong resemblance to a tannin plate, to the presence of which chemical it no doubt owes its virtue.

G. S. P.

[It is somewhat singular that our friend and contributor Mr. Hannaford made the same suggestion to us a few days ago, whilst enjoying a cup of the said beverage. Regarding the panoramic picture forwarded, it is most charming; the subject is one in which the error in perspective does not attract attention, and what is lost theoretically in this respect is more than made up in the extent of angle gained. Such pictures make us more anxious to see the panoramic lens in general use. As a photograph, this is the best we have seen from a tannin plate. In this respect nothing could be better.—Ed.]

Printing Difficulties.

Sir,—The incessant changes rung on the difficulties of printing with unvarying success on albumenized paper, induce me to offer a few remarks on a source of perplexity and annoyance which I have no doubt has puzzled others as well as myself. I allude to a condition of the printing bath, which sometimes appears, although consisting of several ounces of nitrate solution, to lose, somewhat suddenly, the power of giving vigorous prints. My own bath contains ten or twelve ounces, with originally eighty-five grains of fused nitrate of silver to the ounce. On first preparing it, I added a few drops of acetic acid, just sufficient to show a faint reaction upon test paper. After sensitizing about a dozen pieces of paper, 6½ by 4¾ inches, I found all the indications, in the three or four last sheets, of a weakened bath. I could scarcely conceive, with a bath of the size and strength employed, that the abstraction of the silver, by its conversion into chloride, would produce sufficient dilution, to account for my failures, and my opinion was confirmed on pouring the contents of the bath into a glass measure, sufficiently deep to allow of my using a small hydrometer, which soon settled at nearly eighty grains of nitrate of silver to the ounce. On pouring the bath into the measure I saw at once that its contents were not of equal density throughout—that, in fact, the *lowest* stratum of solution not having been disturbed by the process of sensitizing, maintained its normal density, whilst the upper being so repeatedly robbed of its silver, became sufficiently reduced in strength to account for loss of vigour in the prints. On returning the bath into the glass dish, the prints subsequently taken showed all the vigour of the first. The obvious remedy, therefore, for a bath in this condition, is occasional agitation to promote uniform density.—I remain, yours very truly,

Welland Ford, March 18, 1861. H. Fitzroy Pelham.

Glasgow Photographic Society.

Dear Sir,—That you should have been puzzled at the reports of our meetings, I do not wonder; for my own part I feel considerably at being obliged to address you on this matter, but I am bound to make some explanation as to my position.

At the outset it will be necessary to explain that Mr. Cramb is not only the secretary of the society, but the only reporter, even when he himself is actively engaged in the discussion. I now state a few facts which will shew how I have been made to play so ridiculous a part. At the meeting on the first Thursday of February, when Mr. Cramb read his paper on the silver meter question, he and his brother called on the meeting to witness the experiments, if they were what might be called correct. The first was to measure out one drachm of my silver bath; he having done so I remarked that the measure contained more than a drachm, others coinciding in my opinion, *three* drops were then removed, and the meeting was then satisfied that the measure contained only one drachm (mark, three drops out of one drachm) after they had insisted that the first measure was correct, (so much for the *accuracy* of the experiments). I then asked whether they had tried the temperature of the solutions before using the hydrometer, and was told *no*; but that the temperature of the room was about 60°, and *consequently* that of the solutions should be the same. I then said that unless they were certain that the solutions were at 60° when tested by the argentometer, the experiments were valueless.

I am also represented as having said, that I considered the silver meter useless as a test for old baths, while I only said it was useless for *old collodion baths* highly charged with ether and alcohol, (I have always used the argentometer for my printing baths, and consider nothing could answer the purpose better).

As I had not then read Mr. Hughes's paper, I asked Mr. Cramb whether he considered Mr. Hughes's remarks had any reference to what he had said on a previous occasion, and was answered in the affirmative—Mr. Hughes having even quoted Mr. Cramb's words. I then proposed a vote of thanks to Mr. C. for his experiments, and said I was glad the matter had fallen into such able hands, for I was satisfied that no member of our society could use the tongue or handle the pen better than he could.

As to the report of our adjourned meeting on the 14th, it would be simply ridiculous to enter into any explanation of it, as it does not do justice to those gentlemen who differed from Mr. Cramb.

Mr. Macnab, at our last meeting, spoke of this report as being "garbled, one sided, and false," which opinion I most cordially endorse.—I am, yours truly, John Stuart.

120, *Buchanan Street, Glasgow, March* 20, 1861.

[We are glad Mr. Stuart has done justice to the Glasgow Society, which numbers amongst its members some photographers we highly esteem, and relieved it from the implication of endorsing Mr. Cramb's rudeness. We have, from several sources, been informed that the members generally entirely disapprove of Mr. Cramb's attack upon Mr. Hughes and ourselves. —Ed.]

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 20th March, 1861.

Photography has lately received promotion in the army. Our minister of war has decided that an officer of each corps shall be a practical photographer. In the event of a campaign this officer to accompany his corps. These officers are already appointed in the guards, and in several regiments of the first military division. There are many branches of the public service to which photography ought to be attached, and doubtless will be in due time. The war department is always first served with every new and useful invention: other departments have to employ much persuasion and influence ere they can get even the story of their wants listened to. I am not jealous that the military department should be the first authorized patron of our art, on the contrary, I think the good example may be beneficial; but I am annoyed to think that so many other departments, which might derive such important aid from photography, should be allowed to do without it, whereby the cause of knowledge and the public good are the sufferers.

I should be glad to see more specimens forthcoming from your side of the channel, as contributions to our forthcoming Exhibition; but I suppose they will all arrive at the last moment. This is bad policy, and should be avoided if possible. I hope to see British photographic art adequately represented here in May. The opportunity is not to be despised, and professional photographers, especially, will find their interest in contributing specimens.

Experiments which continue to be made on the disinfecting properties of coal-tar, are attended with very satisfactory results. For cesspools and other receptacles of decomposing matters, to which various antiseptics have been applied with equivocal success, coal-tar is found perfectly efficacious, and is now employed to the exclusion of chlorine, charcoal, the salts of lead, zinc, iron, &c.

Phenic acid, one of the many valuable substances eliminated from tar, is also employed as a disinfectant, under circumstances where the use of coal-tar might be attended with some inconvenience. It is very serviceable in anatomical preparations; it is sufficient to place the animal matter in a vessel, the interior sides of which are smeared with the phenic acid; it completely checks fermentation. Water dissolves more of this acid than is generally supposed; as much as 5 per cent. at 60° F., and this solubility may be greatly increased by the addition to the water of 5 to 10 per cent. of alcohol, or of acetic acid. The aqueous solution is useful in skin disease; it instantly destroys the *acarus* of the itch, and ringworm is cured by it. Rubbed upon the skin, it produces a rubefacient action, which continues from 15 to 20 days, without causing ulceration, suppuration, or scar. The pain it causes, lasts about an hour. This application of phenic acid may be found to advantageously supply the place of blisters.

From the numerous researches that have recently been made by many eminent chemists, it is probable that we shall soon arrive at a knowledge of the chemical constitution of steel. It has been the custom to call steel carburet, or, more properly, carbide of iron; but, since the important part that ammonia is found to play in the conversion of iron into steel, the old chemical notion has become greatly modified, if not altogether changed. Steel is obtained either by cementation, the action of carbon upon iron, or by decarbonizing cast iron by a special puddling, but the precise nature of the aceiration, or how it is effected, has never been clearly understood, nor in what the actual difference between iron and steel consists. We know, somewhat vaguely, it is true, that many substances, such as nitrogen, and organic and inorganic substances containing that element, particularly the cyanides, phosphorus, manganese, tungsten, aluminum, &c., exercise a certain influence upon the production and quality of steel, but the modes of action of these various substances, and the nature of their influence, have remained impenetrable mysteries. It has been shown a thousand times that certain kinds of iron always produce steel of the first quality, while other qualities of iron as pure, or perhaps even purer, yield steel of inferior quality. In fact, a great many interesting facts are known concerning steel, but the most important fact of all, the knowledge of its interior constitution, has remained unknown.

Still most chemists consider steel as a carbide of iron, that is, a definite or indefinite compound of iron and carbon: in this sense, steel differs from iron only by an addition of carbon, and from cast-iron by a lesser proportion of iron. The question then is, whether this opinion is well-founded. M. Frêmy, who has carefully studied the matter, answers in the negative on the following grounds:—1. Not a single experiment has clearly demonstrated that steel is simply a combination of iron and carbon. 2. No one has ever succeeded in converting iron into steel by simply placing iron in contact with carbon absolutely free from all foreign influence, such as impurities in the crucible, the action of the elements of the atmosphere, &c. 3. Every kind of steel when dissolved in acids leaves a residue which in no respect resembles pure carbon, but, on the contrary, resembles certain cyanides. 4. Of all methods of carbonizing iron, the simplest consists in submitting the iron to the action of coal-gas; now, when for a sufficient length of time, about two hours, we pass dry coal-gas upon red-hot iron, the latter is converted into a very malleable, fusible, graphitous cast-iron, comparable in every respect to the finest cast-iron produced by charcoal; but it is not converted into steel. Simple carbonization, therefore, produces cast-iron, but not steel; steel is not carbonized iron. M. Frêmy inquires whether steel be not the result of a simple nitrogenization, if steel be not nitrogenized iron: to this he replies emphatically, that it is not. Nitrogenized iron undergoes profound modifications in its properties; it becomes granular and white, but it also retains a degree of malleability; tempering does not harden is; it is not steel.

The next enquiry is, what will result from submitting iron to the double influence of nitrogenization and carbonization; will the result be a nitro-carbide, or a carbo-nitride of iron, a compound of iron, nitrogen and carbon? This third question M. Frêmy resolves without difficulty: he has nitrogenized iron by ammonia, and carbonized it by coal-gas. Thus by the employment of ammonia and coal-gas he had two means of great certainty of regulation, which enabled him to study the successive and simultaneous action of carbon and nitrogen upon iron. This enabled him to undertake a new series of experiments: and he clearly ascertained: 1st. That the action of lighting-gas alone converted iron into cast-iron. 2nd. That the carbonizing action of coal-gas upon iron, previously nitrogenized, gave to the compound the characteristics of steel. 3rd. That the extent or intensity of the acieration depends upon the quantity of nitrogen which has been given primarily to the iron; that an insufficient nitrogenization, no matter how far the carbonization be afterwards carried, gives only an imperfect steel, which leaves much to desire: on the contrary, after a sufficient nitrogenization carbonization produces a steel of very fine grain: that by submitting the red-hot iron to a mixture of ammonia and coal-gas, an acieration is immediately effected varying with the relative proportions of the two gases.

Hints to Colourists.

HARMONIOUS FLESH COLOURING—In colouring flesh our photographic painter too frequently follows a conventional idea, gleaned from some one specimen of his favourite master. One colourist will keep all his flesh greys greenish; another of a violaceous tone; and a third will invariably render them blue: and these followers of the conventional carry out such ideas irrespective of complexions or local peculiarities of surface. Now as the colourist who is ambitious of giving value to his production as a work of art should give especial study to the greys of his flesh colouring, let him throw aside any favourite theory or conventional maxims he may affect, and, placing a model before him, study from nature the varieties of these greys, their local peculiarities; and the modifying influences of light and shade. He will then find that such, although various in character and differing in their tones, are all in harmonious relationship with the local colours of the flesh; for instance, if the complexion be yellowish, the more delicate greys; such as result from the blue veins beneath the skin, will be very decidedly greenish, the more neutral greys which arise from the retiring character of the surface, will also be slightly broken with the yellow of the complexion, and that cool grey which is given by the glossy down of the skin will still be in harmony with the general effect, because it is not peculiar to any part but to the whole of the flesh, although its effect of course becomes more perceptible on surfaces retiring from the light. Of course, this paragraph will be of little value to those who merely *tint* their flesh, in which case the grey tones of the photograph itself may be allowed to represent all the greys, save such as result from the presence of veins.

PREPARING PHOTOGRAPHS FOR CRAYONS.—A very good way of preparing such is to make a mixture of isinglass and cuttle-fish powder, boiling, and well mixing before applying with a flat camel-hair tool. Possibly gum-tragacanth might serve the purpose even better than isinglass. This preparation gives that tooth to the surface, without which it is impossible to apply any body of crayon. Some correspondents, who have made inquiries about photographic colouring in crayons, will find this subject fully treated in a work soon to be published on artistic colouring in all its branches by our esteemed contributor Mr. A. H. Wall.

PAINTING HAIR.—The hard, unnatural, and ugly effect so commonly observed in the colouring of hair in photographic portraits arises from the absence of thought. Study your model and think about what you see, and such defects would soon be as offensive to you as to the educated artist. Observe, where the hair is parted, how softly and imperceptibly the flesh and the hair melt one into another. Note how—in common with all polished bodies—in or near the high lights there is a cool, or decidedly cold tone, according to the nature of the local colour. And observe how, where the hair meets the luminous colours of the flesh, it does not cut hard and keen of edge against the latter, but first melts imperceptibly into the shadow it casts upon the surface beneath it. Then notice how this "cast shadow" grows lighter as it, in its turn, melts into the grey edge peculiar to all shadows on flesh—and so unites beautifully and harmoniously even the darkest parts of the blackets hair to the lightest passage of the most delicate flesh.

Talk in the Studio.

Singular Cause of Fire.—Mr. Negretti recently wrote to the *Times*, and described the curious origin of a fire occurring in the window of his shop, where philosophical instruments were kept. A large lens was suspended in the window, which, acting as a burning-glass, concentrated the sun's rays on to the wood-work, which just happened to be in the focus of the lens, and set it on fire.

The late Duchess of Kent.—A photograph of her Grace the late Duchess of Kent is just in course of publication by M. Claudet, which will be the more highly valued from the fact that she rarely sat for a portrait to any photographic artist.

The Royal Portraits.—We understand that Mr. Mayall has now just completed an entire series of card photographs of the Royal Family. It is unfortunate that, owing to her failing health, the portrait of the late Duchess will not be included, as she was unable to keep an appointment made with Mr. Mayall for the purpose of a sitting.

New American Lens.—Transatlantic photographers are on the *qui vive* about a new lens, invented by, C. C. Harrison the eminent American optician, for producing pictures with a very wide angle of view on flat plates. The description published in the report of the American Society's meeting is not very intelligible; but a committee was appointed to examine, and report on the capabilities of the lens. *Nous verrons.*

Balloon Photography.—At a recent meeting of the American Photographic Society, some new prints were exhibited from a negative taken during a balloon voyage, by Mr. Black of Boston. Our readers will remember that we described some former experiments of Mr. Black, in this direction, undertaken some months ago.

The Ectograph.—Mr. Sutton recently showed us a very pretty positive photograph sent to him by one of his American correspondents. It bears the unexplained name of the Ectograph. Mr. Sutton was not at liberty to publish any details of the method of production; but we are engaged on some experiments for obtaining a similar class of pictures, which we will shortly publish in detail.

Tuition in Colouring.—It may be interesting to many of our readers who are anxious to add the charm of colour to their monochromous productions, to know that our esteemed contributor, Mr. A. H. Wall, has just opened a class for tuition in colouring photographs at 28, Old Bond Street.

Gallo-citrate of Iron Developing in Cold Weather.—A correspondent sends us the following:—During the recent intensely cold weather, I did not find the pyrogallic developer act with sufficient energy, so by way of experiment, I put into it a little protosulphate of iron, about 2 grains to the ounce, which made it all that could be desired for clearness and intensity. As I have not seen such a receipt, I thought it might be worth the attention of some of your readers.

Iron	1 or 2 grains
Pyro	1 „
Citric acid	1 „
Water	1 ounce.

The combination has often been used. Mr. Tunny, at a recent meeting of the Photographic Society of Scotland, gave a formula in which iron and pyrogallic acid are combined, and which he terms gallo-citrate of iron. He regards it as one of the best developers extant. The formula is as follows:—Fifteen grains sulphate of iron, having been dissolved in one ounce of water, is added to another ounce of water containing two grains of pyrogallic acid in solution. A copious precipitate of gallate of iron is formed, which is re-dissolved by adding *quant. suff.* of a saturated solution of citric acid in water. Those who try this will find that for a short time no apparent development takes place; but they will be agreeably surprised by the picture subsequently starting into existence in a most instantaneous manner. When this takes place the development is *completed*, no further length of time seeming to add to its density.

To Correspondents.

R. Gordon.—The yellow spot in your albumenized paper appears to originate in some defect in the texture of the paper. It may, however, have arisen from contact with some solution, possibly hypo, forming the insoluble hyposulphite of silver.

C. F. B.—We will insert your name. There are two especial defects in your picture, which will be easily remedied in future. The views have not been taken so that the images fall exactly in the same place on the ground glass. A tree which in one picture occupies a place on the right, in another occupies the centre of the picture. In such case the images cannot superpose to form a proper stereoscopic image. The other defect is the existence of some yellow spots from imperfect fixation. We are not in the habit of filtering collodion, and never, when we have tried, have obtained any advantage by doing so. We always allow it to clear by subsidence. There is, we believe, an instrument in existence called a "collodion filter," intended especially for this purpose.

J. C. H.—We cannot mention the name of any especial maker in this column, but will write to you.

Clipson Wray.—There are several French photographic journals, *La Lumiere, Cosmos, Revue, Bulletin, Moniteur*, &c. You should determine in which of them you wish to advertise, and then send through an advertisement agent in London.

No. 35.—The best plan to keep the dust out of your portfolio is to connect the flaps at the corners by means of gussets. We shall probably give a description of Harvey's portfolio shortly.

Wm. Lydamore.—The brown precipitate of oxide of silver formed by adding caustic potash to a solution of nitrate of silver, is to be well washed before adding to the bath. Caustic potash is sold in the fused sticks you describe. The streaks of which you speak, running in the direction of the dip, indicate the want of a little more acid in your bath. We shall be very glad to see the sketch and description of the camera stand to which you refer. We have not time to write private letters on subjects which can with propriety be answered in this column.

M. M.—Iron is not suitable as a developer in the dry processes generally; and it is especially unsuited to the development of tannin plates, as it at once turns black from the formation of tannate of iron, which is something like common writing ink. Pyrogallic acid solution, prepared as given in another page should be used. The use of gelatine prior to coating the plate with collodion, is to prevent the film leaving the plate. See Major Russell's article in the present number.

James L.—Common lacquer or spirit varnish and lampblack applied *cold* should be used for the dead black of brass work. If the brass be heated the varnish will dry bright. The authority to which you refer is in error.

J. C. L.—We have never found any bad results from adding a few drops of ammonia to the water in which soluble cotton is being rinsed after thorough washing. It should be however, rinsed a few times more in clean water. We never use less alcohol than ether in the solvents: frequently more. We do not recommend cadmium only as an iodizer, the physical properties it confers are not desirable. Half iodide of cadmium and half of one of the alkaline iodides give good results.

G. W.—Rive paper will give you, *ceteris paribus*, vigorous prints, and Saxe paper soft prints. But much will depend on the negative, the strength of the silver bath, &c.

D. G. Morgan.—To gain the full value of iron as a developer, the collodion should contain a bromide, and very few of the negative collodions sold do contain a bromide. You can use a positive collodion for negatives, but you may probably have difficulty in obtaining quite sufficient density; in that case mix a portion of negative collodion with the positive: most positive collodions do contain a bromide. You can add a bromide to any collodion by dissolving in alcohol and then adding a small portion of the solution to the collodion. Bromide of cadmium would be the best in this case, as being most soluble.

Justitia.—For producing the best transparencies where superposition printing is used, the negative should not be too dense; but somewhat thin and full of detail. Something will, however, depend on the preparation of the sensitive plate for printing on, and on the development.

B. N.—Your picture is spoiled by applying black varnish on the collodion film. We do not approve of black varnshing that side of the positive at all; but, if it be done, the film should always be varnished with a spirit varnish first, so as to prevent the black varnish permeating the collodion film. If you want the picture to be non-inverted, there are other ways of managing it. Perhaps the simplest is to take the picture *through* the glass. Remove the spring from the back shutter of your dark-slide, and place the plate in with the excited film next the back, keeping it firmly in its place by a piece of vulcanized india-rubber at the corners. It will be important to wipe the back of the glass, so that it may have no drops standing on it to refract the light.

W. H. B.—If you will send us your address we will advise you privately, as we can do so more fully than in this column. Of the names you mention No. 1 is best.

Q in the Corner.—The exact strength of the tannin solution is unimportant. See article by Major Russell on the subject in the present number.

W. H. H., in our next.

Stereoscopic Exchange Club.—S. Clifford, Australian House, Hobart Town, desires us to thank those gentlemen who have exchanged with him, and to request them to address Tasmania, instead of Australia, as the former is the correct designation, and the latter might lead to some inconvenience.

E. Morton.—We have no doubt at all of the advantages, theoretical and practical, of the solar camera, and have seen some very fine pictures produced by it. It is quite possible, however, to produce good enlargements without its use. We shall have something to say on the subject shortly.

E. W.—We do not recommend the proto-nitrate of iron for negative development. It gives a silvery white metallic picture, which is a good characteristic in a positive, but is not desirable in a negative. The acetate of iron is a good negative developer.

Photography on Wood.—Mr. Bennett Lowe, whose communication on this subject we published last week, desires us to state that the allusion made in a recent article on this subject, to Mr. Langton having experimented in this direction for some years previous to 1854, was an error

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 134.—*March* 28, 1861.

INTENSIFYING PROCESSES.

An interesting paper on this subject, which was read by Mr. Blanchard at the last meeting of the South London Photographic Society, will be found in another page. There can scarcely be any need to urge the importance of securing, where it is at all possible, a perfect negative at one operation, without the aid of subsequent processes for producing sufficient printing intensity. Where the desired result can be obtained at once, without a secondary process involving trouble and risk, there is no danger, we apprehend, of the photographer resorting to intensifying processes in his regular practice. It is only where there is something to gain by producing the negative at two operations, not otherwise obtainable, that such processes become legitimate and desirable. It so happens, however, that there are several very marked advantages which render these processes desirable and important much more commonly than might at first sight appear. These advantages consist of the facility with which softness, half-tone, and delicacy may be secured in the negative, combined with very short exposure.

The first-mentioned of these qualities as resulting from the operation of intensifying will, at the first glance, startle some of our readers, as they have doubtless been in the habit of associating the idea of hardness with all intensifying processes, and, without a question, that is one of their commonest tendencies when misused. When applied under proper conditions, however, hardness is by no means a legitimate consequence of their use, as we shall show.

One of the simplest methods of intensifying, and one becoming of almost universal application amongst first-class portraitists, is that in which the intensifying is effected before fixing. The negative is developed with iron, and when all the detail is fully brought out the plate is well washed. When viewed by transmitted light at this stage a very perfectly developed negative should be seen, but without anything like sufficient intensity for printing purposes. This has now to be communicated by the use of an organic developer. A two- or three-grain pyrogallic acid solution, with its due proportion of acetic or citric acid, and a few drops of silver solution, is now applied, and the image rapidly begins to blacken and gain intensity, the intensifying by this process being continued until the requisite density is obtained.

There are two or three precautions necessary to be observed in using this method. After washing the plate well from the iron solution, it is desirable to cover it with the pyrogallic solution, and make it run freely without greasy lines, *before adding the silver solution*, otherwise there is danger of staining the plate. The silver solution should be pure, *not from the bath*, but prepared for the purpose, about twenty grains to the ounce is strong enough. If it be used from the bath there is danger of irregular reduction. In hot weather there is danger of a foggy deposit on the shadows taking place during the intensifying. Should this occur the plate should be washed at once, and a judicious application of cyanide will generally remove the nascent foggy deposit. There are two methods, however, of preventing its formation, the first the free use of citric acid in the pyrogallic acid solution; and a second method, perhaps less known, but still more efficacious, is the application of a solution of iodine to the film after washing away the iron developer, exposing the plate for a few seconds to light, again washing, and then applying the intensifying solution of pyrogallic acid and silver. This method prevents the formation of the deposit on the shadows and allows also of considerable intensity being more easily attained.

The chief advantage of this process arises out of the fact that it permits a bromide to be used in the collodion, and thus secures all the advantages which the presence of a bromide can confer,—extreme sensitiveness, softness, and cleanliness. With a simply iodized collodion the advantages of an iron developer are not very marked; and with a pyrogallic acid developer, the advantages of a bromide are not always very striking. But with a bromized collodion a much softer picture is obtained by means of iron development, in about one-third or one-half the exposure that would be required for a simply iodized collodion with a pyrogallic acid developer. We are fully aware that it is possible to have a simply iodized collodion in such a fine condition that the most perfect negative possible may be produced by pyrogallic acid development; and with also, the shortest possible exposure. But we also know, that these are conditions very difficult of attainment, certainly not always attainable at will, and when secured, the collodion cannot be kept in that condition. If it be so one day, it loses sensitiveness by the next, and goes on deteriorating daily. Another difficulty also exists with the simply iodized collodion, it is the fact that when it is in the finest possible condition as regards sensitiveness and half-tone, it is also in its most sensitive condition to the influence of all damaging agencies, and it is almost impossible to produce a clean picture; fog, comets, stars, and all kinds of unsought meteorological and astronomical phenomena abound on the plate. It is a certain fact within our personal and editorial experience, that there is more complaint as to the rapid loss of sensitiveness, and the prevalence of all kinds of spots in the simply iodized collodions of two of the most celebrated makers, than exists in any other case. The presence of a bromide changes all this. The highest state of sensitiveness, the power of yielding perfect half-tone, and the facility for obtaining perfectly clean pictures, remain uniform and undeteriorated for months.

The qualities we have just described remind us of one of the primary advantages to be derived from the use of intensifying processes, and the one to which Mr. Blanchard chiefly addressed himself the other evening,—their value as adjuncts to instantaneous photography. This word instantaneous, is a somewhat indefinite one as used in photography. There can be no doubt but that in its absolute sense it would refer to an indivisible point of time; but it is applied in photography to any rapid exposure in which there is no intentional prolongation. An exposure as rapidly effected as the lens can be uncovered and covered, no matter what mechanical appliances be used for the purpose, is generally called instantaneous; although there can be no doubt but there is an immense disproportion between the time of exposure effected by such contrivances as that of Mr. Warren De la Rue for photographing the sun, or by Mr. Skaife for photographing a rocket in its flight, and that effected by taking off and putting on the cap of the lens by the hand's most rapid movement. Still, for the least rapid of these, in order to obtain a good negative, it will be generally desirable to develop with iron and intensify afterwards.

The pictures of Mr. Wilson of Aberdeen, which certainly rank amongst the finest instantaneous pictures with which we are acquainted, are developed with iron, and subsequently intensified, and if we are informed rightly by a method not commonly used. As wé have not seen this published, and are not, we believe, violating any confidence, we may briefly state his method. The exposed plate is developed with a tolerably strong solution of iron, until all the details are fully out, and as much intensity is obtained as that application of the iron will produce. It is then washed, but not fixed, and placed in a box. It will remain in this condition without entire dessication for some time, and allow other views of the rapidly declining sun—we are referring especially to the sunsets—to be secured, before it was quite sunk beneath the surface of the water. The whole of the plates are then intensified at leisure. To do this, a small quantity of silver solution, either from the bath or otherwise, —a fresh ten or twenty grain solution would be best—is poured a few times on and off the plate until it flows freely and evenly; this is then followed by a second application of the iron developing solution, to reduce the silver and produce the requisite intensity. As will be seen, this process is similar in character to that which we have just described as largely practised by professional portraitists, the difference being, that in the intensification of the latter, an organic developer is used, and in Mr. Wilson's method the reduction is more entirely inorganic.

It will be observed that all the methods given by Mr. Blanchard are used after the picture is fixed, whilst those to which we have referred are applied to tho film before the film of iodide of silver has been removed by cyanide or hyposulphite of soda, and bear more analogy, therefore, to development proper. When the intensifying is effected at this stage of the operation there is no danger whatever of producing hardness, if the plate have received anything like proper exposure; as the half tones and faint shadows receive their fair share of the subsequent reduction as well as the higher lights. In all cases, however, where the intensifying is effected after fixation there is a tendency to greater reduction on the high lights than on the half tones, and hardness is often the result. It is important, therefore, that in all cases where intensifying after fixing be practised a fully exposed picture, full of half tone, be obtained as a basis of operations.

The process most allied to ordinary development of those mentioned by Mr. Blanchard is the one given last in his paper, and the one to which he gave the preference. It is, unquestionably the easiest to manage. and the one most under control as regards the character of its results. The process was first recommended by Messrs. Barreswil and Davanno in their *Chimie Photographique* in the year 1854. They there recommend a satuiated solution of iodino in water to be applied to the film, which was then to be exposed to the light, and afterwards treated with a solution of gallic acid and silver. Iodine is, however, very sparingly soluble in water, but freely in solutions of the alkaline iodides; and they subsequently recommend a solution of one grain of iodine and two grains of iodide of potassium in an ounce of water, to be applied to the plate in a similar manner, following with a solution of pyrogallic acid and silver. Mr. Blanchard recommends the employment of a strong or a weak solution of iodine, just according to the amount of intensifying required. There is one circumstance in connection with this formula we may mention, having ourselves used it largely and successfully; there is no necessity to expose the film of iodide of silver to the light, as the process may be effected in a dark room without any such exposure.

There is one important precaution which applies to this and all intensifying processes—the imperative necessity of washing thoroughly between the application of each distinct solution—otherwise stains will inevitably occur. There is another hint we may give here as applying to all processes in which intensity is produced by the reduction of silver; it is the fact that if the silver be rapidly reduced there is a tendency to a greater precipitation on the high lights than on the half tones, whilst if it be slowly and steadily reduced, the deposit is harmoniously distributed over the whole.

The processes in which the bichloride of mercury is used as an intensifying agent, are more difficult to manage, and, except in judicious hands, do not always give good results. Complaints are made of the film becoming rotten and leaving the glass; and the negatives obtained are often very hard and unsatisfactory. Nevertheless, some of the finest pictures we have seen were produced from negatives intensified with iodide of mercury. This was one of the first intensifying processes proposed, being suggested in 1853 or 1854 by Mr. Maxwell Lyte; the use of bichloride of mercury had already been proposed by Mr. Archer, aud various blackening processes were proposed about the same period. Professor Donny proposed a method which assisted to keep the film on the plate; having bleached and thickened the deposit by means of bichloride of mercury, instead of, after washing, applying some other solution which might have a further tendency to destroy the film whilst it darkened the deposit, he applied a solution of gum arabic, and, whilst the film was still moist, submitted it to the action of a current of sulphuretted hydrogen gas, by which means he obtained at once an intense, black negative. Few persons will, however, we apprehend, avail themselves of this troublesome and offensive aid.

Where the use of mercury as an intensifier is resorted to, its peculiar dangers must be met by the use of judicious treatment, and the employment of a proper collodion. Hardness must be avoided by the use of a sufficiently bromized collodion, giving abundance of detail in the original deposit, and the tendency of the film to break, by employing a collodion which adheres well to the plate. Allowing the plate to dry will also materially aid this, and will give the additional advantage of greater delicacy and sharpness than can by possibility be obtained by an increased deposit whilst the plate is in a wet, absorbent, and spongy condition. We have some experiments in progress for meeting the difficulty presented by the film leaving the plate, which, if successful we shall shortly lay before our readers.

A variety of other intensifying agents have been proposed, the majority or all of which we have tried. Amongst these, we name chloride of gold, chloride of platinum, hydrosulphate of ammonia, &c. The chief action of these and some others, is to change or darken the colour of the image by reflected light, but havo little power in repelling the influence of actinic rays by transmission, and we do not recommend their adoption in any case, except where the slightest possible increase of intensity is desirable. As they appear in all cases to blacken the film very much, they are very deceptive.

THE TANNIN PROCESS.

We call the attention of our readers to some further hints on this process, given in a letter by Major Russell, in another column. We may suggest also that we have heard, within the last day or two, of a very efficient method practised by a skilful amateur of meeting the chief difficulty—the tendency of the film to leave the plate. He adds to the tannin solution a little gum-arabic, and also a portion of citric acid. This, we understand, gives some additional good qualities to the negative, and prevents the film leaving the plate in the developing, fixing, or washing. We hope in another number to be able to state the proportions: in the meantime, we commend the method to the attention of of our experimental readers.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analylsis.

Next in importance to iodine and the iodides stand bromine and the bromides. These being prepared from bromine, we will describe that element first.

Bromine occurs mostly in sea water, and certain mineral springs, although it has been met with in Mexico and some parts of Brittany in combination with silver. It is prepared generally from sea water; the mother-liquor of the water, which has been evaporated for the purpose of separating the different salts, has chlorine gas passed through it as long as the yellow colour increases in depth. The chlorine decomposes the metallic bromide into chloride and free bromine, the latter producing the colour. An excess of chlorine must be avoided, as that would produce chloride of bromine and thereby decolourise the liquid. Ether is then added, and the mixture well shaken together. On standing, the ether rises to the top of the solution, coloured hyacinth red by the bromine which it has absorbed. It is then to be decanted and shaken with solution of caustic potash, which converts the bromine into bromide and bromate of potassium. The solution is evaporated to dryness, ignited and distilled with peroxide of manganese and sulphuric acid, when bromine passes over; it must be collected in water.

The bromine so prepared contains water, and generally a small quantity of chlorine. From the latter it is separated by washing with a large quantity of water, and it may then be dried by distillation over chloride of calcium.

Pure bromine is a very dense mobile liquid, three times as heavy as an equal bulk of water. It is of a deep brownish red, nearly black colour. It freezes at 20° C. forming a yellowish brown crystalline mass, and boils at 45° C., being converted into a yellowish red vapour. It has an extremely powerful and offensive odour, resembling chlorine, but worse. Hence its name from the Greek βρῶμος, an offensive odour. Its vapour when inhaled is less injurious than that of chlorine, and if very dilute may be breathed with perfect impunity; large quantities, however, give rise to cough, giddiness, bleeding at the nose, headache, &c., and if still more concentrated would prove fatal. It has a sharp, burning taste, and is very poisonous in the liquid state, one drop proving instantly fatal to a bird. Bromine in small quantities stains the skin of a yellow or brown colour, which if strong can only be removed with the skin itself. Applied to the skin in larger quantities it corrodes it and produces violent inflammation. It corrodes wood, cork, and other organic substances, and acts upon vegetable colours in a similar manner to chlorine. The reaction between bromine and starch is not so delicate as that between iodine and starch, although the latter substance is frequently used in the laboratory, as a convenient test for this element. When a solution containing free bromine is mixed with a little starch paste, the latter becomes of a strong orange yellow colour. It dissolves in 33 parts of water, forming a yellowish-red solution, smelling like bromine.

This solution, which is frequently employed in the Daguerreotype process, is made simply by shaking up an excess of bromine with distilled water. The surplus bromine sinks to the bottom, and the supernatant liquid will be the desired solution. It loses bromine when exposed to the air, and when kept for any length of time becomes acid. Bromine is soluble in alcohol to a greater extent than in water, and still more so in ether. In its other properties it greatly resembles iodine and chlorine, standing midway between the two in its affinities and chemical characteristics.

The most important compounds of bromine are the bromides of potassium, ammonium, cadmium, and silver.

Bromide of Potassium is prepared in several ways—the best plan is to decompose bromide of iron by means of carbonate of potash. Pure iron filings are to be placed in a flask under water, and bromine added to the liquid drop by drop, waiting till the action has ceased with one quantity before more bromine is added. The iron will gradually be dissolved, forming a pale green solution. (The addition of bromine must not be continued long enough to dissolve all the iron; some of the metal must be left at the bottom of the flask). When sufficient bromine has been added, the solution must be filtered and preserved in a well-stoppered bottle for use. A knowledge of the combining proportions of bromine and iron will at once tell how much of each to take in order to prepare a given quantity of bromide of iron. The equivalent, or combining proportion of bromine, is 80, and of iron is 28, the two bodies must therefore be mixed together in these proportions (or rather there should be a trifling excess of iron) in order to produce 108 parts of bromide of iron; and this 108 parts of bromide of iron, when completely decomposed by carbonate of potash, will yield 119 parts of bromide of potassium, the equivalent of potassium being 39. The decomposition of the iron salt is effected as follows:—An equivalent quantity of carbonate of potash, as pure as possible, is to be dissolved in distilled water, and the solution of iodide of iron being raised to the boiling point in a flask over a sand bath or spirit lamp, the carbonate of potash solution is to be gradually poured into the iron salt, and when the oxide of iron is completely precipitated, the liquid must be rapidly filtered. Now place the clear solution in a clean evaporating dish, and gently evaporate it nearly to dryness. When it is sufficiently concentrated for a drop, taken out by means of a glass rod and placed on a cold glass plate to crystallize on cooling, remove the dish from the fire, and place it aside in a cool place to crystallize, covering it over with a sheet of blotting-paper to keep out the dust. In a few hours the bottom of the dish will be seen to be covered with a mass of crystals, which must be removed and drained in a funnel. These crystals may be completely purified by dissolving them in water and then evaporating the liquid to the crystallizing point again. If the solution, before evaporating it this second time, has an alkaline re-action to test paper, this must be removed by the addition of a little hydrobromic acid.

Bromide of potassium forms brilliant cubical crystals, resembling the corresponding iodine salt. It fuses without decomposition when heated, and has a sharp taste. It dissolves in water, readily producing great diminution of temperature, and is much more soluble in hot than in cold water. It is only slightly soluble in alcohol. 100 parts of bromide of potassium yield 160 parts of bromide of silver when entirely decomposed.

The impurities in the commercial salt are likely to be of the character we have already mentioned as occurring in iodide of potassium. The methods of purification given under that head will, therefore, be quite applicable for the purification of bromide of potassium.

Bromide of Ammonium.—If, in the process above given for the preparation of bromide of potassium from bromide of iron, carbonate of ammonia had been used instead of carbonate of potash, the result would have been the ammonium salt. Bromide of ammonium greatly resembles the corresponding iodide, and may be purified in a similar manner. It is a colourless salt crystallizing in long crystals, having a sharp saline taste. When heated they evaporate without fusion. Exposed to the air the crystals become slightly yellow, and have then an acid reaction, owing to the formation of a small quantity of hydrobromite of ammonia. Bromide of ammonium is very soluble in water, and also more soluble in alcohol and ether than the potassium salt.

Bromide of Cadmium may be readily prepared by placing 80 parts by weight of bromine under water, and gradually adding thereto 60 parts of metallic cadmium in fine filings, shaking the whole together. As soon as the combination has ceased, and all the bromine has disappeared, filter the solution from the few grains of cadmium which will remain undissolved, and evaporate it down over a water bath until a crystalline scum forms on the surface, then allow the solution to cool and crystallize. Bromide of cadmium thus formed will be pure, provided pure materials were used in its preparation. It forms white efflorescent crystals easily soluble in water, alcohol, and ether. The crystals of this salt differ from those of the iodide of cadmium, in that they contain four atoms of water, the iodide being anhydrous. This peculiarity must be borne in mind when calculations are being made in which the amount of iodine or bromine in the cadium salts form elements in the enquiry.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Balance.—That every portion of a picture should exist, not in independent scraps, like so much patchwork, but in harmonious relationship, as parts of a *whole*, is acknowledged in every branch of art. For this reason the equilibrium of forms, lights, shades, colours, &c., are studiously sought, so that the interest or attention of a spectator is not shut up in a corner, but carried by skilful composition over the whole surface, each part being properly balanced, although displaying a sufficient amount of variety and subserviency of position, proportion, &c., to carry out the artist's primary design. This proper arrangement of parts being a matter of great importance, the artistic photographer in arranging accessories, grouping figures, or selecting his point of view, always aims at securing a well-balanced composition. If he finds the general mass of light or dark crowded into one corner of his focussing-glass, he shifts his position to bring in sufficient light or dark to balance the same; should all the interest be confined to one point, he moves again to take in some object possessing that degree of interest which will be subservient to the general design, and at the same time restore the lost equilibrium, and so on. It must be evident that in endeavouring to secure the quality now under notice, a lens which commands a wide angle of view is pre-eminently desirable. Conscious of this, when Mr. Sutton's "panoramic" lens made its first appearance, I hailed its advent with no small pleasure, and, although I have not myself had the opportunity of practically testing this apparatus, I do believe that it will fulfil our expectations, and give us far more power over the pictorial resources of art than we have hitherto possessed. It is now, I believe, in in the hands of one of our most skilful opticians, and will receive that fair and perfect test which I fear it has not yet had, and which may, I hope, be crowned with the most thorough success. If we can secure a good lens, giving us so much subject that we may choose exactly what portions we shall retain, and what remove, the balance of parts will be more easily grasped, and other artistic advantages secured which in this place I have no right to enumerate, although in the course of these articles the reader will duly recognise them.* With his present appliances the photographer should first consider the form his intended picture will take. This determined, he should calculate what objects it will include, what amount of interest they have, and how they will be related as light or shade in his completed production; and this done, let him then consider how the various parts will *balance*, never, however, losing sight of the more important design embodied in the expression of the sentiment, character, or story of the whole. The operator who has been quite unaccustomed to this bit of mental exertion will think it a great bore, and feel a very strong inclination to make excuses to his conscience for declining the effort, but if he persevere, the mind will by-and-by perform its part of the work almost as instinctively as the hand, while his productions, by displaying more evidence of intellectual culture and thought will win greater esteem and respect both for himself and his art. Bear in mind, as Ruskin says, that "it is the essence of composition that everything should be in a determined place, perform an intended part, *and act in that part advantageously for everything that is connected with it.*" In thus re-producing in symmetrical order the various parts, one great danger must be avoided, viz., *formality*, it is not necessary that one part be balanced by another which resembles it, or that the parts be arranged after the fashion of the "three jolly butcher boys, all of a row;" nor, in short, that *variety*, the essence of the picturesque, be at all lost sight of.

* Since writing the above a very fine set of glasses, securing an angle of 70°, has been shown me. It was manufactured by Dallmeyer, and covered splendidly.

Base-line.—A term for the line represented by the bottom of the picture. The geometrical plane. (See *Perspective.*)

Beauty.—Although this subject has been so learnedly discussed by our great metaphysicians, that none but the bold venture upon its investigation, a few passing remarks will scarcely be out of place here. The term has received the most extensive application, and originated no little controversy; and as to the quality of abstract beauty I have now within my reach a dozen good or eminent authorities, who in treating the subject contradict each other, and themselves more or less, at almost every step of their progress, and leave us, hapless readers, at their last pages in greater darkness, and far more perplexed than we were before. The term beauty includes all that is pleasing or agreeable to the senses; some trace its origin to the imagination; others to associations; others to moral superiority; some to the conventional only, and others to mere physical conditions. Sir Joshua Reynolds asserted that it was never to be found in extremes; Lord Jeffrey, without much fear of contradiction, that it was the "reverse of ugliness;" Haydon thought it had its origin mentally, physically, and morally "*altogether* in woman." The fact is, I expect, that we must be content to recognise many varieties of beauty, without expecting to trace them all to any one source. Close ties unite even the most opposite kinds of beauty, and with each many are associated. Like a painting, in which all the opposites of lights and darks, forms and colours, are united into one harmonious whole, each kind of beauty is made up of many and various elements. We hear, for instance, the liquid sweetness of whispered music breathing through some soft-voiced instrument, and straight there comes stealing, unconsciously perhaps, into our dreaming memory the ripple of a little stream tripping with glancing feet over the murmuring pebbles, strewing its way in the peaceful quietude of a solitary; and there blends with this the low sweet sigh which floated away with our earliest words of love; and there comes too the memory of exquisitely delicate perfumes, allied *somehow* with such faint low sounds, and such tender gentle emotions; and then, faint with extreme delicacy, come whisperings of the pure and lovely prismatic colours, just tinging some pearly cloud; and thus these images of beauty, all different, all alike, become so mingled together that the languid thoughts refuse to separate them, and we only recognise their presence by the holy sweetness which steals into our hearts, filling them with indefinite emotions of tenderness and love, until full of instinctive gratitude we turn to the Great Creator of a universe so full of loveliness and beauty, thanking him with passionate earnestness for the glorious privilege of human life. Such is the power of beauty, which, translated into a more tangible form speaks to both heart and mind in the language of art, the language I would fain urge photographers to learn and to speak.

Greek art gave us an ideal beauty, a beauty which you thought about before you felt it well, which only reached the heart through the head; but our more modern masters go direct to the heart: beauty of form, mere physical beauty, bounded the Grecian's ambition; we have learnt to love the poetry of spiritual truth, to reproduce that beauty of nature with which is associated all beauty of every kind. There is no beauty in falsehood; Satan, the type of ugliness, is also said to be "the father of lies." It is not the *truthfulness* of photography which tends to mar the beauty of its productions, far, far from it. Nature is prodigal of beauty, and we have but to acquire or cultivate the discernment which we call *taste*, and that power which we call *art*—recognising beauty in whatever guise it may appear—we may mirror faithfully not only nature's outward form, but its very soul, seizing the modest expression of the wee shy wild flowers in their little grassy nest, and the grandeur and might expresed in the boundless ocean, or the sublimity of sky-piercing mountains. The *parrot* photographer, who thinks his sole virtue that of imitation, may mock at the nobler aims of art, and laugh to scorn the ambition which strives to elevate his calling; but he is not, and never will be, even in the most degraded sense of that much-abused term, an artist. The *artist* photographer will cultivate his taste for beauty, and seek inspiration from its presence wherever it may be found; and as Charles Swain tells us—

> "The presence of the Beautiful
> Takes inward shape of every kind!
> As *Music*—which leaves language dull—
> Is *Painting* to the Blind!"

With which, by way of hint, I will quit the subject, important and interesting though it be.

Bird's-eye View.—A view taken from an eminence, in which the horizontal line is very near the top of the picture. Such views are far from beautiful in a pictorial sense, although frequently adopted where it is desirable to combine some of the qualities of a map with those of the picture.

Bizarre.—A term used to describe that which is grotesque, capricious or extravagant.

Black.—Black being representative of the photographer's extreme dark, should, like white, which represents the other extreme, be jealously hoarded. Masses of black tend to decrease the vigour of the shades, just as I have shown that masses of white rob the high lights of force. Sparingly used black and white are the elements of brilliancy, boldness, and vigour; lavishly used, they destroy these qualities. In nature the range of tones and shades which exist between the dazzling brilliancy of white sunlight, and the intense blackness of a total deprivation of light, is indeed a vast one, and when we consider how few are the tones which separate the white of paper—the photograph's highest light—*seen as it usually is in a weak light*, from a black surface *reflecting light*, it must be at once apparent how extremely choice we should be with both our white and black, instead of seeking the intense pictures still too generally admired among photographers. Black is the complementary of white, that is to say, when placed in juxtaposition the white appears more brilliant, especially at the point of contact, than it really is, and the black darker. Acting upon this hint, we are enabled greatly to extend our scale in forcing the effect of the two extremes by contrast, bringing the focus of dark and the focus of light together, and graduating from the extremes thus obtained.

Boldness.—The opposite of insipidity or tameness (See *Vigour*).

Brilliancy.—Applied to the sparkling luminous effect secured by the judicious management of a picture's chiaroscuro &c.

THE CAMPHINE OR BENZINE WAXED-PAPER PROCESS.

By using camphine or benzine as the solvent for the wax, the impure portion is thrown down, and the pure part only retained in solution. This constitutes the chief element of success in this process, as it obviates the granulated appearance, which is the great drawback of the ordinary wax-paper. Camphine is greatly preferable to common turpentine for this purpose.

Paper prepared with benzine is said to require less exposure in the camera, and to yield more intense blacks in the negative. But whether prepared with benzine or camphine, the paper is very much more sensitive than ordinary wax-paper.

Papier Saxe is the best for this process. Hollingworth's thin is not so good, and has a water-mark, which shows through the negative, and prints on the positive. The paper must be cut to the size required, and the face or smoothest side marked with a cross at one corner with a black-lead pencil. It is important always to float the marked side first on the different solutions, and to have a guide for placing the paper right in the dark-slide or double-back prior to exposure.

Excellent benzine may be had of Bolton, Holborn Bars; and pure wax, in half-a-crown cakes, of Brecknell and Turner, Haymarket.

The formulæ (in a much-improved shape) and the various manipulations are as follow:—

Camphine or Benzine Waxing Solution.—Put 300 grains wax, scraped fine, and 20 fluid ounces benzine or camphine into a quart bottle, and stand it before a fire, shaking occasionally, until the wax is dissolved. Set aside to cool, then add by degrees 80 grains iodine, and agitate. (It is not advisable to employ excess of wax or iodine in this stage of the process.) Let the whole stand for a week, to allow any portion of the wax to precipitate; then filter through double paper, and the solution is fit for use. Pour sufficient of this liquid into a flat porcelain dish, scrupulously clean and dry; take one of the papers by the opposite corners, and lay the marked side on the solution, first letting the middle of the paper touch the liquid; then gradually drop the corner held by the right hand, and next that in the left hand, to avoid air bubbles. Should any form, raise up one corner of the paper with a pair of horn forceps till the bubble is arrived at, and then lower it again. When the paper is thoroughly saturated, immerse it, using a glass rod in the left hand, and a glass triangle in the right. Pass the triangle over the paper, and press it against the bottom of the dish, so as to remove air bubbles from the surface of the sheet. Proceed with half-a-dozen sheets in this way; more than this number should not be in the dish at the same time. After letting them remain in the liquid for five minutes, or thereabout, turn them all over together, so that the first put in will be uppermost. Take the horn forceps, and raise this sheet by one corner, holding it over the dish to drip till it has nearly ceased. Then thrust a large pin through the upper angle, and stick it into the edge of a deal shelf, so that the paper may be suspended with its lower corner resting on blotting paper. Of course, the place must be clean, and perfectly free from dust. When all the papers have been thus treated, proceed with six more; and when they have been hung up, take down the first six, and press them between clean blotting paper, and hang them up in another part of the room till quite dry.

The waxing liquid will serve till all used up, therefore return the residue into the bottle through a filter. The dish should be immediately washed out, and any adherent wax rubbed off with paper, if necessary. The same dish, if kept perfectly clean, will do for the subsequent operations of iodizing, sensitizing, and developing. Put the prepared papers away in a portfolio, till required for iodizing, previous to which warm them slightly before a fire.

The Iodizing Solution.—320 grains iodide, and 40 grains bromide of potassium, dissolved in 20 fluid ounces of whey. (This is at the rate of 18 grains to the ounce, a strength which should not be exceeded. The French operators, followed by Mr. Sisson, obtain first-rate results, with 10 grains of iodide and 2 of bromide to each ounce of whey, after short exposures. 12½ grains iodide and 2½ grains bromide would work well.) Filter, and after use, return into the stock bottle through filtering paper. Immerse the papers, sheet by sheet, in this bath, and let them remain in about twenty minutes in warm summer weather, half-an-hour in mild weather, and one hour in cold weather. Adhere to the rule of not having more than half-a-dozen sheets in the bath at the same time. Take each out separately, hold to drip, press between blotting paper, or between the leaves of a blotting book, to be kept specially for the purpose, and hang up till quite dry. They will keep for more than twelve months without deterioration, if not exposed to damp.

The Sensitizing Bath.—Dissolve 400 grains of nitrate of silver in 9 ounces water, and 4 grains iodide of potassium in one ounce water; add the latter to the former, stirring with a glass rod till the precipitate is dissolved. Then add 5 grains citric acid, dissolved in 3 drachms crystallizable acetic acid, and filter through double paper. This bath must not be exposed to day-light, and improves by keeping. After use, return it to the bottle through a filter. To sensiize the paper, float it on the solution, marked side downwards, till the dark colour disappears, then turn it over and float the other side till it has acquired a uniform primrose colour. Raise it with a pair of horn forceps, let it drip, and place it in a dish containing as much water as will cover it well; give the dish a rocking motion for half a minute, then if the paper is intended for exposure next day, blot it off in a separate blotting-book to be used for this purpose only, aud expose to dry. If wanted for longer keeping, give the papers a second washing in another water, blot off, and dry, and they will perhaps keep for a week in moderately warm weather. Sensitize the papers at night by the light of one candle. When quite dry, they may be placed in the double back or dark slide ready for exposure. If put in damp, they will crease. Extra papers should be kept in a portfolio aud subjected to pressure. The washing waters should be put into a bottle with a spoonful of salt to convert the nitrate they contain into chloride of silver, after which the water should be thrown away.

Exposure.—The time of exposure is pretty much the same as for a collodio-albumen plate, but is best ascertained by experiment. Do not expose in a bad light, and be sure not to under-expose. The papers will keep till the day after exposure, if pressed tightly between the leaves of a blotting-book. If the development can conveniently take place on the same evening, it is advisable uot to defer it, particularly if three or four days have elapsed since the sensitizing.

Developing Solution.—Put one drachm of gallic acid and twenty ounces of filtered rain or soft water iuto a clean bottle, expose before a fire, or stand it on a hob, shaking occasionally till the gallic acid is dissolved. Add six or eight pieces of camphor to keep it better, and to ensure clean lights in the negatives. Before use, carefully filter the requisite quantity, pour it into a dish, and add one drop of a 30-grain aceto-nitrate solution to each ounce. In order to develope the exposed papers, float them on this bath, face downwards, carefully avoiding air bubbles. Take one paper at a time, float it, and when the sheet lies quite flat on the surface, and the image begins to appear, raise it with the horn forceps at one corner, turn it over, and immerse it face upwards. Proceed in the same way with the others. Four quarter sheets may be developed together in ten ounces of solution. If there is any tendency in the papers to float on the surface, it is because they are not sufficiently saturated, and they must be kept under with the glass triangle, until they remain beneath. They may then be left until the whole of the details are perfectly developed, when, if the skies are not black enough, a few more drops of silver solution should be added to bring up the intensity. This addition of silver must be cautiously made, for if too much be used, the lights will acquire a dingy appearance. When the skies look intensely black, and the image is slightly over-developed, the negative must be well washed in two changes of water, and may then be fixed as usual. The intensity is afterwards much reduced in the hypo bath. Under-exposed pictures can be treated with a two-grain pyrogallic solution with two drops of aceto-nitrate to the ounce, and when the details are well out, can be returned to the gallic acid solution. Sometimes the paper acquires a dirty yellow colour in developing, but this is of no consequence; indeed, some of the best negatives are of this complexion.

The Fixing.—Dissolve one ounce of hyposulphite of soda in eight ounces of water, and immerse the negative in it. After a dozen papers have beeu cleared in this bath, it must be put aside, and another made. When the iodide of silver has been dissolved out, wash the negative in running water for three or four hours. Finally press between blotting paper, and dry in a warm place, or before a fire.

The fixing can be deferred indefinitely, so that the tourist need not trouble himself with that operation until he returns home.

The final Waxing.—This is easily performed. Each negative is laid in a dish of hot, melted wax, and immediately becomes saturated. It is then raised, allowed to drip, placed between two sheets of blotting-paper, and ironed with a moderately hot iron. The process is now complete.

Have a shallow tray made of block-tin, fitting into a tin vessel or reservoir to hold hot water, about one and a half or two inches deep, and having a spout with a hinged cover at one corner. The apparatus, made by a tin-worker, will cost seven or eight shillings. Set it quite level, pour boiling water into the reservoir about half an inch deep, and set a spirit-lamp underneath. Place a few lumps of wax in the tray, and when they become liquefied the negative is laid carefully upon it, aud is at once saturated, as before mentioned.

In working this process, the dishes and apparatus must be extremely cleau, and the manipulation carefully performed. With the formulæ here given, and a proper amount of exposure, the tourist may always make sure of obtaining a good negative, which (as M. Blot says) "will give pictures with pure whites, and blacks of perfect intensity, with a delicacy which rivals that of albumenized glass, without its hardness and excessively sharp lines."

The original formulæ of M. Tillard, add to the first or waxiug solution, two ounces of cold drawn castor oil, which is in many respects objectionable. The object of this addition is to prevent granulation in the negative, but should this result appear, it may be guarded against by steeping the papers for 10 or 15 minutes in a preparatory bath, made by boiling 30 grains of Irish moss or carrageen, in a pint of water for five minutes, and filtering. With a few bits of camphor in it, this preparation will keep indefinitely, and may be used to the last drop. When dry, the papers may be placed in the benzine or camphine waxing solution. But in most instances, this precaution will be found unnecessary.

R. A. R.

INTENSIFYING PROCESSES CONSIDERED AS ADJUNCTS TO INSTANTANEOUS PHOTOGRAPHY.

BY VALENTINE BLANCHARD.*

All who have beheld the glorious productions of Wilson, of Aberdeen, and the instantaneous sea and sky photographs of Le Grey, must be impressed by the conviction that the future of artistic photography lies not in giving forth to the expectant world delicate primrose or white skies, with the hills so sharp in outline that the thought of the consequences attendant upon a fall upon them makes us quite uncomfortable; middle distance, generally pronounced by the uninitiated to be ice covered with snow, and which only the connoisseur knows to be the photographer's hieroglyph for water, and the foreground made up of black masses dotted with white, known only by general outline to be trees. Photographs of this well known class will soon be covered with the dust of oblivion. Much has been said in defence of photography, During its early struggles its artistic shortcomings were explained away, and the dilletante exclaimed, in order to judge fairly this wonderful art, that has assumed the proportions of Hercules whilst still in swaddling clothes, we must start afresh. All the time-honoured rules, the study of which only has given us our present knowledge on art matters, are useless, for this new art sets them all at defiance.

By degrees the taste in photographic matters became insensibly depraved, and for several years the productions most commended were those where the *manipulative* skill was most apparent. The lens that produced a result upon the sitter as powerful as that effected by the ghost of Hamlet's father, aud made—

> "Each particular hair stand on end
> Like quills upon the fretful porcupine,"

was the one "applauded to the echo." A mania for black tones followed, and was succeeded by one for landscapes of

* Read at a meeting of the South London Photographic Society on the evening of Thursday, March 21, 1861.

gigantic proportions. All these efforts of the unsatisfied speculative mind have not been in vain; but they have been too much in a wrong direction. The French, with a truer taste than ourselves, were dissatisfied with the larger landscape productions, and instead of devoting themselves to this branch of photography, pointed their lenses towards the façades of their magnificent cathedrals. They have, in consequence, produced *pictures* the like of which had never been seen since the world began. The skies in these pictures only make more clear and distinct—

"The high embowered roof
With antick pillars massy proof
And storied windows richly dight."

Many of them are, indeed, so perfect in every sense that they have (to borrow again from the immortal Milton) "dissolved us into ecstacies."

Le Grey is the man who has spanned the gulf that separated photography from the fine arts. We regard him as the pioneer of the new era in photography, and Wilson and a few others have formed the advanced guard. When we look at Wilson's later productions, and see that water—usually so imperfect and naked in photographs—can be produced with all its undulations, its thousand lights and shadows faithfully pourtrayed. When we see it proven that the sun—generally regarded as so fierce in some of his moods—has calmly looked on while the daring photographer has "taken a sight" at him, and even has smiled upon his efforts, and left the impress of his beaming face upon the sensitive plate. When cloudy sky and stormy sea can be portrayed with equal facility, we cannot help feeling that the future before us in photography lies in the perfecting of every means and appliance that can tend to make instantaneous pictures of every size easy of production. As one of the most difficult operations in instantaneous photography is the bringing up of the image to a sufficient degree of intensity we propose to devote our attention this evening to those of the many intensifying processes which we have practically tested. In doing so, we feel no apology necessary. Our chief aim is to cause discussion upon this important part of all instantaneous processes. We shall simply record our own experiments, and doubt not but that in the discussion much valuable information from our practical members will be elicited as to the best means of getting over the difficulties which beset most of the intensifying processes.

At the outset, we would say that if it be possible to bring the picture up at once into anything like a printable condition, we would most certainly not adopt any of the after methods we purpose mentioning. The best means of producing negatives with the requisite intensity is to employ a bath quite neutral, a collodion made with at least as much alcohol as ether; in many cases we would use 2 parts of alcohol, sp. gr. ·800, to one of ether, ·750, iodized with iodide of cadmium 4½ grs., bromide of cadmium 1½ grs. to each ounce of plain collodion.

We consider the preparation of the cotton for this collodion a most important matter, as so much of the after success depends upon the temperature at which it is made. That which we have employed was made with weak acids, at a temperature just below the dissolving point. We have not time now to go into the formula, as we have other things to consider. We hope to do so, however, on some other occasion.

The developer we employ is as follows:—

Iron	30 grs.
Acetic acid	15 ,,
Acetate of soda	1½ ,,
Water	1 oz.

With the collodion we have described, and this developer, we secure an image which comes up slowly, gradually acquiring during the operation what appears to the eye a fine black image, but which, when fixed and brought out to the light, shows that fine peach-like bloom which is so great a charm in negatives produced by the pyrogallic acid. The application of pyro, and a few drops of nitrate of silver completes the operation.

Could we always succeed with this process in securing as much density as is desirable, our task would soon be over; but unfortunately there are many subjects where this totally fails; therefore the need of one of the many after processes of intensifying which we will now proceed to describe. We beg, however, to say, before we go further, that we are not going to announce anything new or startling. We shall simply record our experiments, and send round results produced as nearly as possible at the same time, and under the same circumstances, so that the processes may be fairly tested side by side.

The first one is produced by the agency of a saturated solution of bichloride of mercury, and, after washing the plate, a few drops of a saturated solution of hypo in half an ounce of water is poured over, and the plate well washed. This plan answers well for many subjects; but the tendency is to produce harshness unless the picture has received a slight excess of exposure. The same objection applies to the application of a weak solution of ammonia after the treatment with the chloride of mercury. The great objection to this, or any plan where mercury is employed, is the tendency the film has to split off in drying. This can only be remedied by rejecting any collodion that is at all contractile, and employing one containing not less than five and a half grains of really soluble pyroxyline to the ounce. Another evil, scarcely less than the one just named, is the production of crapy lines in the negative when dry. The remedy for this is a collodion of equal parts of alcohol and ether, and to use solvents as free from water as possible. Crapy marks in a negative indicate invariably the presence of water in the collodion.

The next plan we will mention is one that, a few years ago, was quite a favourite with us. After the application of pyro and silver, should anything further be required, we poured over a very weak solution of bichloride of mercury, draining it off and pouring it on two or three times, until the surface appeared covered by an even coating of black. We did not allow the image to whiten, but washed immediately. On holding the negative up to the light much that was very weak, especially in the half tones and lighter shadows, were brought up, while the powdery nature of the film permitted the light to act much more powerfully than would be imagined, judging from the appearance of the negative. This application of a weak solution of bichloride of mercury for so short a time does not make the film tender, and one of the greatest difficulties is thus overcome.

The next we will mention is the application of iodide of mercury. If a weak solution of bichloride of mercury be poured over the image, and, after washing, a solution of iodide of potassium is spread over in like manner, a yellow image is formed, caused by the precipitation of iodide of mercury upon the silver image. If these solutions are poured over alternately twice or thrice, perfect chemical opacity will be produced in the high lights of the negative, and, by comparing the back of the picture with the front, it will be seen from its conversion into a bright yellow, that the image is composed of iodide of silver as well as mercury. This kind of picture is not at all desirable in an instantaneous process; we would, therefore, recommend a different plan. If we add iodide of potassium by degrees to a solution of bichloride of mercury, a dense scarlet precipitate is thrown down. The clear liquid left after subsiding will produce the yellow image, but still frequently with too much density. There is also a danger of producing marks and stains in pouring on which no after treatment will remove. But if we continue to add iodide of potassium we shall find this dense red precipitate gradually taken up, until it is all dissolved in the excess of iodide of potassium. If we now apply this solution to a negative we shall find its fierce propensities very much curbed. The first effect is to produce blackening, and it goes on gradually until a very harmonious negative is produced. This method has many advantages over the other applications of mercury. If you obtain a well developed positive, with all the detail plainly visible after very careful washing, it can be put in the plate box and left until you reach home; for it acts as well upon the dry as upon the wet surface. Of course it is necessary to wet the film with water before the application of the solution.

The last method we shall mention is one that in our hands has given the best results, affording at the same time the greatest facility of modification. It is the application of an aqueous solution of iodine. We have never seen this plan given in any of the journals, and we felt assured it is known but to few. Tincture of iodine has long been recommended, and, when only a slight increase of density is desired, it answers very well, followed by pyro and silver. The advantage of the new method is, that you can secure as much or as little intensity as you may require by employing a strong or weak solution. In using alcoholic tincture of iodine great difficulty is experienced in making the alcoholic solution unite with the aqueous one, and frequently stains are produced during the operation. By the following plan the difficulty is obviated :—

The method of producing a solution of iodine in water is, doubtless, known to many; but for the benefit of those not familiar with the plan, we will describe it. If a drachm of iodine be put into a 4-oz. bottle, no solution will take place; but if iodide of potassium be dropped in, a change is immediately produced; first, a yellow colour is produced; on adding more, a beautiful crimson appears, until, on frequent additions, the whole of the iodine is dissolved, and a deep-coloured solution remains. This stock solution can be diluted according to the intensity required. We always judge by the colour the strength necessary to produce any effect we want. If a negative require but a little vigour, then we apply a solution in colour between sherry and port; and let it remain on a few seconds. On holding the negative up to the light, a very decided change will have been produced. More intensity will have been imparted to all parts of the negative, without having changed in any material degree the general appearance of the image on the surface. If, however, the picture be thin, then a strong solution may be applied, and poured on and off until the image comes out as a beautiful positive full of delicate half tones; and of a very pale primrose colour. A little pyro and silver will complete the operation.

One great peculiarity we have noticed in negatives so produced is, that on holding up the primrose image to the light, a ruby colour, inclining to the complimentary purple, is seen. But on looking at the surface, nothing but the bright primrose colour is visible.

There are many other processes possibly yielding good results in the hands of those who have given attention to their peculiar requirements. Among others, there is the chloride of palladium, but as it is more expensive, and does not yield results better than some we have mentioned, we have not introduced it. Indeed, the opinion of those competent to judge is, that it is not equal to several we have described.

Our task is now done. Believing that the *modus operandi* of the veriest tyro may convey some hint to the thoughtful experimentalist, and may be instructive to many—if only to serve as a warning beacon, pointing out some photographic shoal or quicksand to the wary voyager—or confirming the established chart, we shall sit down content to learn in the discussion how little or how much is considered useful to the many. And if, however imperfectly our task may have been performed you will take the will for the deed, we shall be more than repaid.

Proceedings of Societies.

South London Photographic Society.

The monthly meeting of this society was held in St. Peter's School Room, Walworth Road, on the evening of Thursday, the 21st. The Rev. F. F. Statham, B.A., F.G.S., in the chair.

The minutes of a previous meeting having been read, the following gentlemen were elected members of the society :— Messrs. Price, Warner, Quentery, Gridley, and Samuel Fry.

The Chairman called attention to Mr. Mudd's fine picture of "Coniston Falls," which had been selected by the sub-committee, appointed for the purpose, as the presentation print to the members of the society, and proposed a vote of thanks to Mr. Mudd for placing such a valuable picture within the means of the society.

The Secretary called attention to some prints which presented, in the first-place, advantages to the painter who might wish to colour them, from the delicacy of the detail in foliage, &c., having perfect definition without any approach to blackness, and a second advantage in their suitability for transparencies from their vigour and beauty by transmitted light. These characteristics were obtained by placing the side of the paper which had not come in contact with the silver sensitizing solution next the negative in the printing-frame, and causing the printing to take place through the texture of the paper.

Mr. G. Wharton Simpson called attention to a panoramic picture by Mr. Penny, of Cheltenham, produced by two exposures in succession on one dry plate. (See Photographic News, p. 141.) The plate from which this picture was propuced was prepared by the tannin process. The picture elicited much admiration, both for the ingenuity of the idea, and the excellence of the photograph.

Mr. Valentine Blanchard then read a paper on "Intensifying Processes as Adjuncts to Instantaneous Photography." (See page 150). Several instantaneous stereo negatives of street scenes, with moving vehicles and foot passengers, and prints from them, were passed round to illustrate the processes.

Mr. Samuel Fry said he had been struck with the regular progress in the value of the processes explained by Mr. Blanchard as illustrated by the photographs exhibited, and especially with the fact, if he rightly understood it, that such pictures could be taken in such weather. That they were absolutely instantaneous was manifested by the fact that no blurring was apparent in the moving figures in the busy traffic of a London street scene, and this with London light in a March day was certainly striking and important. In his own experiments in instantaneous photography he had had, like Mr. Blanchard, difficulty in getting sufficient printing vigour without recourse to intensifying processes. Pyrogallic acid as a developer would generally give sufficient intensity, but it required longer exposures. Iron undoubtedly was of the utmost value as a developer in instantaneous work. The process of intensifying which he used most, and found successful, was analagous to one of those mentioned by Mr. Blanchard. It consisted in the application of a solution of bichloride of mercury, followed by a solution of hydrosulphate of ammonia. This produced a negative of a yellowish brown colour, of very considerable printing intensity. The plan last-mentioned by Mr. Blanchard, which gave results much superior to the others, appeared to be all which could be desired. He thought, in all instantaneous photography, too much importance could not be attached to the value of a bromo-iodized collodion and iron development. Regarding Mr. Blanchard's specimens, he should certainly have liked to have seen something larger than stereo plates, but he knew this was hoping too much at this time of the year, and nothing could be more suitable than those exhibited for illustrating the processes described.

Mr. Blanchard explained that in order to make the experiments as satisfactory and complete as possible, he had thought it important that they should all be taken under, as nearly as possible, the same circumstances and conditions. He had discarded other specimens he had, in order to produce the whole before them in one day, and as rapidly as possible, one after another. Press of professional duties had driven him to the the last day, and the whole of the negatives had been taken, intensified and finished during the day, and the pictures from them had been printed, toned, fixed, washed and mounted since four o'clock that afternoon. Of course nothing could be said of their permanency, but they served the present purpose.

Mr. Hughes remarked that if the practice of instantaneous processes were found possible with large plates, the future of photography would assume altogether a different aspect to what it had hitherto done. The time had been when the great complaints in regard to any attempts in this direction had been of the extreme hardness and deficiency of half-tone. The difficulty now seemed to lie in the other direction. All who had worked with a bromo-iodized collodion in a weak light were familiar with the thin phantom image, and it certainly was an interesting point to determine the best methods of intensifying such images so as to retain delicacy whilst acquiring strength. Regarding the use of bi-chloride of mercury, it had generally been regarded as having a tendency to fill up delicate details, and ignore half-tone. Mr. Hardwich had remarked that its utility was chiefly confined to copies of engravings in which half tone was not necessary. The experiments and specimens of Mr. Blanchard possessed a peculiar interest as showing the different results given under the same circumstances by the different agencies employed. In regard to the methods themselves, many present had been long familiar with them, but perhaps no one before had given such a valuable comparative view of their respective degrees of fitness for the work required of them. The last-named process in the paper appeared undoubtedly the best, as giving the most vigour combined with delicacy. The process there named, although probably older and better known than Mr. Blanchard fancied, was still not so well known as it ought to be. It was given in Mr. Hardwich's fifth edition, and spoken of with confidence, but in the last edition some doubts were expressed of its value. In a practical question like this, and one the value of which would largely depend on manipulation, Mr. Blanchard was probably a better authority than Mr. Hardwich. The great value of these experiments, was the confidence with which they shewed such methods might be adopted, the great power in this direction, which they illustrated as lying in reserve. The use of bi-chloride of mercury, it was known to most of them, gave continued risk of destroyed films; all might go right until the drying, and then the picture was found to be a "thing of shreds and patches." He had been struck with one remark of Mr. Blanchard's, that relating to the use of cadmium alone as an iodizer for alcoholic collodion. That was certainly a different doctrine to that entertained generally, and promulgated by the great advocate of alcoholic collodion, Mr. Sutton, as it was considered that the combined use of cadmium and excess of alcohol, had a tendency to make the collodion unmanageable by gelatinization. He would be glad to know in what proportions Mr. Blanchard had used the alcohol.

Mr. Blanchard stated, that he had used the ether and alcohol in equal proportions, and had found he obtained a most limpid fluid collodion with cadmium.

Mr. Hughes remarked that these proportions scarcely constituted what was called alcoholic collodion. In conclusion, he would remark that almost all the intensifying processes had been proposed years ago, and were quite old, but that in the present state of photography it was sometimes quite as useful to revive past knowledge as to seek for the unknown.

Mr. Fry said there was another plan of getting vigorous negatives from faint negatives having no printing qualities. He referrred to the method of producing first a transparent positive by superposition from the the weak negative, and from that transparent positive a negative: by using processes giving intensity at each stage, any amount of vigour in the final negative might be obtained. He had called at King's College recently, and Mr. Sutton had there shown him a negative, taken, he believed, by Mr. Llewellyn, by the oxymel process; it was so weak and thin that it would have been useless for printing purposes. A transparency taken from it, however, by superposition, on a tannin plate, was full of vigour and intensity. From this, of course, the next plate would be a negative. The plan was extremely valuable, and might be effected either by superposition, or copying in the camera.

Mr. G. Wharton Simpson wished to endorse Mr. Fry's remarks as to the value of this process, either for multiplying negatives the same size, or producing them on an enlarged or reduced scale. From even a very weak positive, so long as it possessed all the detail properly marked, however faintly, very vigourous negatives might be obtained. There was a case in point which it was worth while to recall in support of this position; he referred to the fact that one of the illustrations of Mr. Piazzi Smythe's work on Teneriffe was produced to the number of some thousands, from a glass positive which had passed some months of its existence with black varnish at the back. This on being removed permitted a transparency to be produced by transmission, and from the transparency the negatives required. This process had some advantages over intensifying processes upon the original picture, from the fact that it involved no risk to the original, whilst all intensifying processes certainly involved more or less of danger to the film. Any number of negatives of any size could, however, by this method of reproduction, be obtained without risk to the original, and with such varying degrees of intensity as occasion should suggest. In regard to the use of a cadmium iodized with alcoholic collodion, having experimented somewhat largely in that direction, he might remark that with a proper pyroxyline cadmium might be used with the solvents in equal proportions without any difficulty, he had used it with two proportions of absolute alcohol to one of ether, but there was a tendency in that case to become glutinous and unmanageable, and wherever that proportion was used he preferred half of cadmium and half of some alkaline iodide in the collodion. The proportions originally proposed by Mr. Sutton in the alcoholic collodion proper, were, he believed, four-fifths of absolute alcohol to one of ether, and in that case, cadmium could not be used with advantage.

Mr. Eidmann said, he did not think it probable that a good negative could be obtained from a weak positive as stated. He thought, if the half tone was weak in the original, it would be entirely absent in copies.

Mr. Simpson assured Mr. Eidmann, that this was not a question of probability, but of fact. The method was well known to many photographers. Of course, the reproduction could not possess detail that was absolutely absent in the original; but all that was there could be obtained in a more vigorous degree in the negative. He had repeatedly done it himself, especially for producing enlargements.

Mr. Eidmann referred to the advantages of a mixture of gallic and pyrogallic acid with silver, as an intensifying process.

Mr. Hannaford asked Mr. Blanchard the proportions of iodide and bromide he had used in his collodion.

Mr. Blanchard stated, that he had used four grains and a half of iodide, and one grain and a half of bromide.

Mr. Hannaford remarked, that the proportion of bromide was larger than was usually recommended. He had used as much as a grain, but not more, and then he found a tendency in the picture to be too weak; but that very quality was a recommendation where intensifying processes were used, as the picture required for such purposes should be full of detail, but did not require intensity. The greatest evil of all processes in which intensity was gained by a thick deposit of silver was the fact that fine lines and delicate details got clogged and filled up. The great advantage of a good intensifying process was, that it allowed the collodion to be used in its most sensitive form, without regard to intensity, rapid exposure being the only consideration. He had recently been making some experiments with the use first of a solution of bichloride of mercury, followed by a very dilute solution of iodide of potassium, and was pleased with the promise it yielded. There was one point of importance to know in connection with this subject; it was, that if too much intensity had been obtained, it could be reduced by applying a stronger solution of iodide of potassium to the film, as iodide of mercury was soluble in excess of iodide of potassium. Care, however, should be used not to carry this too far, or the intensity might become so much reduced that it could not be regained. There was another point which might be worth attention; he thought if the film were dried before applying the solution of mercury, the danger to the film might be less. He threw this out as a suggestion.

Mr. Blanchard said one of the negatives before the meeting had been done so.

Mr. Hannaford added in regard to the question of obtaining a vigorous negative from a weak and useless one, he had done it himself often, and he had also done the reverse, obtained a soft negative from one which was too intense. The process of reproduction in that way admitted of much latitude in the result to be obtained, with a little knowledge and skill almost any class of picture might be thus reproduced. He would conclude by suggesting that some attention be given to intensifying processes in connection with dry plates, and recommended that subject of the attention of the Experimental Committee.

The Chairman made the remark, that if the soluble cotton for a collodion were of suitable quality, made with weak acids at a high temperature, it might without disadvantage be iodized with cadmium, even though the solvents were in the proportion of five parts of alcohol to three of ether, or even six parts of alcohol to three of ether, and referred to a gentleman who was very successful who used such a collodion.

Mr. Simpson remarked that Mr. Hardwich had, in his last edition, given a formula for pyroxyline intended especially for a cadmium collodion. Referring to the question of the proportion of bromide, he might remark that he had just had a letter from Major Russell, in which he recommended for his tannin process as much as two grains to the ounce, and three of iodide.

Mr. Blanchard remarked, in reference to the reduction of intensity by a strong solution of iodide of potassium, the continued use of the mercury solution would have a similar effect.

After some further conversation, a paper on "Sharpness," by Mr. Wall, was announced for the next meeting; and, after the usual votes of thanks, the proceedings terminated.

Photographic Notes and Queries.

Drying Box for Prepared Plates.

Sir,—As we should always be ready to impart improvements in the photographic line to our fellow photographers, I beg your permission to submit the following description of a box I have used for some time with great success.

The box is made of double tin three-eights of an inch all round, and also a partition of the same in the middle. This tin box is enclosed in a mahogany one, in order to keep in all the heat. It is advisable of course to have the outer box made of some hard wood that heat will not warp. The tin is made to project about half an inch above the box to allow for the cover shutting down light-tight. In a suitable corner on the top of this tin box I put a hole as large as possible with a screw to fit into it. Through this hole the hot water is poured in—a small funnel is of course necessary for doing it. At the bottom corner of the box on the side I put another hole with a small pipe fitted to it, projecting about half an inch beyond the wooden box also fitted with a screw, which is for emptying the tin box when the water has become cold.

On the sides of the tin box are placed small pieces of tin, top and bottom, about one inch long, and projecting just enough to slide the plate on. Of course, these pieces of tin must be put on an angle, as the plate will have to stand so for draining. After having prepared my plate I simply slide it down in the box (having put previously two or three thicknesses of blotting-paper all along the bottom)—when I find that the plate is dry in from six to eight minutes, according, of course, to the temperature, which I find never beyond "blood heat," even with boiling water, so that the films are not at all injured. In this manner I have prepared numbers of plates, and have found them equal to those dried spontaneously. I have found that the best plan is to prepare say a dozen plates before putting in the boiling water, as it gives the films a little time for draining.

The box I have holds sixteen plates, any number of course in proportion to the size of the box. I allow one inch between each plate for draining room. The cost of such a box, including lock, handles, and black japanning of the tin, was eighteen shillings; but, for those living in a large town, it could be made, I should think, for twelve shillings.

I was quite surprised, and at the same time glad, to read in your News the other day, that Mr. Fry was patronizing a similar box, as I had thought that mine was perhaps the only one of its kind.

I would just add, that I have practised with success Mr. Howard's plan of the "Fothergill Dry Process," as given in your News a week or two back; and would advise all those who want to adopt a dry process to try the "Fothergill," with Keene's collodion, as I believe, and I have found it so, the most simple and most sure process, if cleanliness is strictly observed. I have not tried the "Tannin Process," but will do so very shortly, especially if, as they say, it beats the "Fothergill" in exposure.—Yours very truly, J. A. Clements.

Ventnor, Isle of Wight, March 22, 1861.

Folding Backgrounds.

Sir,—Could you, or any of your correspondents, inform me how to make a background 6 feet by 6 feet, with a hood about 3 feet by 6 feet at the top, to increase or diminish the top light, so as to be able to fold it up in lengths of about 3 feet, and carry it to friends' houses? (The wood, I suppose, might be managed in some way with hinges, but the calico painted as generally ordered, I should think, would flake up, and show all creases made in it.) Also, the probable cost?—I remain, yours sincerely, W. H. H.

Clapton, March 17, 1861.

[Some of our readers may be able to give our correspondent a hint. A background painted in distemper would be apt to crack. Painting in oil and flatting might answer the purpose; or a very wide woollen fabric, such as is used for making ladies' mantles, might answer.—Ed.]

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 26th March, 1861.

M. Fargier has communicated to our Photographic Society the details of his carbon-printing process. The essential condition of success is that the mixture of solution of gelatine and carbon be very intimate. When this result is attained, the mixture is spread on a flat piece of glass, and then slowly dried by a gentle heat. Once dry, the plate is exposed under a negative in the ordinary printing-frame. Three or four minutes exposure in the sun will be found sufficient; the result may be estimated by approximation; it may, however, be arrived at exactly by placing a piece of nitrated paper in the pressure frame, for the time required for exposure is nearly the same both for sensitized paper and the glass bearing the mixture. On removal from the printing-frame the latter is covered with non-iodized collodion, in sufficient quantity to form a film as thick as a sheet of paper. This done, the glass plate is put into warm water, collodion uppermost; the latter soon swells up, and is retained only on its edges, which may be detached from the glass by the thumbnail; the water penetrating under the film removes the soluble portion of the mixture, and the carbon it contains; the collodion film floats in the liquid, the glass is then lifted out, the water being renewed two or three times, and lastly the picture is transferred to a sheet of gelatined paper.

M. Peligot proposes that the residues of photographic operations be treated in the following manner:—These residues, which contain hyposulphite of soda, pyrogallic acid, sulphate of iron, cyanide of potassium, acetic acid, and salts of silver and of gold, &c., are usually treated with *liver of sulphur*, which precipitates the last three metals in the state of sulphides. The employment of liver of sulphur presents many objections; its bad odour is very objectionable; and the sulphuretted hydrogen is apt to spoil photographs exposed to its influence. And the presence of sulphide of iron renders the reduction of salts of gold and silver more difficult. A better method consists in introducing into the residues (which are generally alkaline), a thin plate of zinc, and leaving it there for four and twenty hours. The silver and gold are precipitated in the metallic state. It may be ascertained if the precipitation be complete by taking a small quantity of the clear liquid and boiling it with hydrochloric acid. It will produce a deposit of sulphur which should disappear on the addition of a few drops of nitric acid. If any silver remains in the liquor, it will be precipitated under the form of chloride of silver. The black powder of gold and silver is then treated with diluted sulphuric acid, and washed upon a filter. Some of the metals adheres to the plate of zinc, this may be removed by brushing it off under water. The zinc plate will then serve for fresh precipitations. The filter is burned, and the mixed metals, with a little salt of soda and borax, are melted in a clay crucible. The metals treated with nitric acid yield nitrate of silver; the gold remaining in a pulverulent state. This method appears to be the most simple, practicable, and economical yet made known.

M. Niepce de Saint Victor suggests that paper for receiving the image in the solar camera be prepared with chloride of silver, as usual, but that after a short exposure the image be developed with gallate of lead. A cold saturated solution of gallic acid is prepared, to which is added some gallate of lead. When boiled it dissolves a certain quantity of this salt, it is then filtered, and when cold a few drops of acetic acid are added. The chlorided paper will require only a few seconds exposure in the camera, as with iodized paper. The image appears very quickly in the developing bath. The whites remain pure, while the blacks acquire great intensity. The proofs are toned with chloride of gold, and fixed in the usual manner.

A very interesting series of researches has been made by M. Jules Regnault, on metallic amalgams, and the origin of their chemical properties. In a preceeding report, he has stated that the chemical properties of amalgamated zinc and cadmium resemble the thermal phenomena accomplished at the moment when these two bodies unite with mercury. His new researches have led him to generalize these relations; they extend to a great number of metals, and prove that the one, as zinc for instance, rise in the scale of positive affinities, while others, as cadmium, on the contrary, become lower by amalgamation. Among these metals, those which become electro-positive on becoming allied with mercury, are the following:—

Iron	Zinc	Copper
Nickel	Tin	Lead
Cobalt	Antimony	Bismuth

Zinc, tin, and lead are the only ones among these bodies which, by simple contact, and without auxiliary, physical, or chemical action, enter into combination with mercury. M. Regnault has proved that the amalgamation of tin and lead is accompanied in the same manner as with zinc, by a striking reduction of temperature. Therefore, in the three cases where the temperatures can be measured directly during the reaction, we find that the positive affinity of the compound increases when its heat of constitution augments. We may reasonably conclude that the other amalgamated metals in which identical properties are observed, owe them to the same cause. The comparison of their latent heats of fusion and of the chemical rank which they occupy is very favourable to this view. Iron, nickel, and cobalt have an affinity for mercury very slightly different from that of zinc, and as, also, their latent heat is unquestionably superior, the increase in the positive affinity of the amalgams is a result of the heat confined in the latter. The electro-chemical properties of the amalgamated metals, iron, nickel, and cobalt, is also explained on the same principles. For if, on the one hand, their latent heat is generally inferior to that of zinc, on the other hand they unite with mercury by virtue of an affinity so feeble, that the formation of the alloy, as can be verified for tin and even for lead, is a source of reduced temperature. As to the metals with cogeneric cadmium, that is, those which disengage heat upon amalgamating, and which, according to the theory, ought to become lower in the order of affinities, they are found in the group of metals placed at a great distance from mercury by their electro-positive character. Their combination with the latter is the result of an energetic affinity, and as their heat of fusion seems otherwise to be feeble, the production of heat during the reaction manifests itself with a remarkable intensity. Potassium and sodium, the amalgamation of which takes place with such a disengagement of heat that the temperature reaches the point of incandesence, has supplied the means of giving a new control to these ideas. Conclusive experiments also prove that the amalgam of potassium and sodium formed in virtue of these powerful affinities, are negative relatively to the pure metals. Mr. Regnault concludes, from his researches, that whenever a metal is amalgamated, its position in the scale of affinities undergoes a modification. The result may be in the opposite direction, even for neighbouring metals, for it depends both on the chemical function of the metal, and on its latent heat of fusion. If there is a reduction of temperature during the combination of the metal with the mercury, if, consequently, the heat of the constitution of the amalgam is greater than that of the metal, the latter rises in the order of affinities. When the whole of the thermic phenomena are reversed, when the alloy is formed wiih disengagement of heat, the amalgamated metal is negative relatively to the free metal.

M. Charles Tissier suggests a means of refining metals, especially copper, by the agency of sodium. The difficulty experienced in removing the last traces of sulphur, arsenic, phosphorus, carbon, and silicium from the metals with which they are combined, is well known; often impairing their good qualities to a very great degree. The manufacture of aluminium has led to the production of sodium in large quantities, and it may now be obtained at a very moderate price. Sodium is admirably adapted to the ultimate refining of a good number of metals; the expense of employing it in the refining of copper, even to the extent of a 200th part, which is an extreme quantity, would not militate against its use on the score of economy. Sodium acts by forming with sulphur, phosphorus and arsenic, alkaline sulphates, phosphates, and arseniates, which rise to the surface of the metal in the form of scoriæ. The carbon and silicium are in their turn removed by the soda formed during the operation; and, in separating, the one forms oxide of carbon, the other alkaline silicate. Antimony, bismuth, and the analogous metals which have much more affinity for sodium than copper has, form with it very oxydisable alloys, which produce a cupellation similar to that effected by lead: lastly, the oxydule of copper, which very often contributes to acidify this metal, is immediately decomposed by this energetic agent.

The promptitude with which the vapour of sodium acts when passed through the metal in a state of fusion, leads to the idea that its employment will play a great part in metallurgy, and that it will greatly simplify the purification of cast-iron, and its conversion into malleable iron.

THE TANNIN PROCESS.

Sir,—Within the last few days I have found out that some statements contained in my letter to you last week require a little correction. The plan for working the tannin process without the coating of gelatine, is not to be depended on. With some collodions it works well, but does not answer with others, especially if thick, so I cannot recommend dispensing with the gelatine.

I have often kept the glasses covered with gelatine in the manner described, and always without injury until very lately, when some which had been long kept showed round black spots in the negative, apparently from fungus, caused probably by damp air getting access to the plates. A glass simply cleansed and kept in the same box was affected in the same way. It appears from this, that it is best to use plates recently covered with gelatine, if they cannot be kept perfectly dry. The tannin solution may be used of almost any strength, but I find that the stronger the solution, the more acid should be used in the silver developing fluid. If 30 grains of tannin to the ounce be employed, 20 grains of citric acids should be dissolved with 10 grains of nitrate of silver.—I am, sir, your obedient servant, C. Russell.

Stubbers, West Romford, 25 *March*, 1861.

Sir,—There is but one very assailable imperfection in the tannin process, viz., the wrinkling of the film; this I can obviate by drying the sensitized and and washed film before putting on the tannin (in stereo plates), it also seems to be an unnecessary strength to have a 30-grain bath in this process, for I have a 15-grain one which answers with the tannin process; and probably an excess of silver would be sufficient if of far smaller strength than this—may it not be the same with all *dry* processes? for the concentrated silver bath is only available in the wet collodion to help to impress the film and aid in development; if you have not heard of a better plan for doctoring the film, you may probably like to make it known to your readers.—I am, sir, yours, &c. W. Bartholomew.

Fareham, March 23, 1861.

[One of the objects of the application of the tannin solution is, we apprehend, to keep open the pores of the collodion film; and in applying after drying the film this object must be lost.—Ed.]

Talk in the Studio.

Photographic Soiree.—The President and Council of the Photographic Society have just issued cards of invitation for a soiree to be held at King's College, on the 4th of April next. It is expected that many of the photographs now exhibited in Pall Mall will be taken to King's College for the occasion.

Photographic Exhibition.—The Exhibition in Pall Mall closes on the 30th inst.

Photographic Grouping.—The *Athenæum* has not a high opinion of the artistic powers of photographers generally. Speaking of a photograph of the officers of the 84th Regiment by Messrs. Agnew and Co., of Manchester, it says, "it is not only a good specimen of photography, but remarkable as illustrating the success of a common-sense course of proceeding in the matter of placing the sitters—generally the very point in which the operators fail most lamentably, for the simple reason that composition is one of the most subtle branches of an artist's study—a quality, indeed, of which there have been fewer masters than any other. The operator has placed, or allowed them to place themselves, the whole body of the officers, over forty in number, the majority standing, a few seated in front. With the felicity that sometimes attends chromatic combinations in the kaleidoscope, they are perfectly grouped in simple masses.

Patent for Photographs by Artificial Light.—A patent has been taken, in the United States, by Messrs. P. F. and W. S. Dodge, of Cambridge, Massachussetts, for taking Photographs by Artificial Light. Their claim runs as follows:—We claim the combining with an artificial light, and one or more series of reflectors, of an intercepting medium or plate, when so arranged with respect to the object, and the light and reflectors, as to intercept or soften the dazzling rays from the light, and allow the unobstructed rays to pass from the light upon the reflector and thence upon the sitter, substantially as described. We also claim the peculiar arrangement of the upper and side reflectors together, so that the side reflectors cast their reflected rays upon the object, while the upper reflectors cast not only the rays thrown upon it by the light upon the object, but also throws upon the object the reflected rays from the side mirrors, all as set forth."

Pyroglycerine.—A substance resembling pyroxyline in some of its characteristics, and of a most powerfully explosive character, called pyroglycerine, and also "explosive glonoin," has been obtained by the action of a mixture of nitric and sulphuric acids upon syruppy glycerine. The process closely resembles that by which gun-cotton, and other similar explosive compounds, are obtained by the action of the same acids on cotton wool, and other substances composed largely of carbon. Mr. Ferris, an American chemist, nearly lost his hearing by the accidental explosion of about thirty grains of the pyroglycerine. A single large drop will explode with a report as loud as that of a gun.

Panoramic Photography.—The importance of producing pictures with a much wider angle of view than is usually obtained is beginning to excite much more attention than formerly. A correspondent last week described a method of taking such views at two operations very ingeniously; but that, of course, could only be used where the error in perspective did not become striking. We saw a few days ago an exquisite picture taken by Mr. Wilson, of Aberdeen, with one of Mr. Dallmeyer's triple lenses. This picture included the widest angle we have yet seen effected on a flat surface, the angle being nearly 70 degrees. The picture contained clouds, &c. very perfectly defined, and appear to have been instantaneous. There was also considerable depth of focus. There was, unquestionably, some falling off of light at the corners; but we understand the lense was used with its full aperture, a condition for which it is not usually intended. The rapidity of action which an instantaneous picture indicates, is certainly a feature we had not been led to anticipate in these lenses. We have not yet tried them ourselves, but hope to do so shortly. The sight of this picture certainly affords an additional inducement to do so.

Photography and Morbid Anatomy.—Mr. Geoffroy Saint-Hiliare has just presented to the French Academy of Science a photograph of a youth, fourteen years of age, who has a peculiar malformation, which has been called "péadelphe." His right leg is divided into two limbs, both terminated by feet, which, however, point in opposite directions.

To Correspondents.

*** Articles on Working Wet Collodion in the Field, by Mr. Vernon Heath; on Printing on Ivory, by Mr. Samuel Fry; on Albumenized Paper, by Mr. Maxwell Lyte, and several other articles and letters from correspondents are compelled, from press of matter, to stand over until next week.

F. N. S., Cambridge.—Our correspondent asks if it be possible to take negatives on glass with albumen alone. We are somewhat at a loss as to his meaning. If he mean by "alone" without collodion as well, there have been two or three articles in our columns within the last few weeks, giving details. If this be not his meaning, he must be a little more explicit, and we shall be glad to answer him further. There is no separate work on transparencies that we know of. There have been many articles in the Photographic News from time to time, and there will be another, more complete one in the course of a week or two.

A Learner should be careful to follow formulæ carefully if he desire good results. In the instructions given in the Almanac we were careful in directing the addition of silver to the pyrogallic solution, to say, "not from the bath," but from a solution prepared for the purpose. The use of silver from the bath under such circumstances, often causes fogging, especially if the bath be an old one. It is often difficult to obtain a sufficiently dense negative by iron alone, unless the collodion and bath be in an especial condition suited to the purpose. See leader in this number, also paper by Mr. Blanchard, and discussion at the last South London meeting.

Juvenis.—The spots on your print are manifestly from something which has accidentally been splashed on to the paper. Hyposulphite of soda coming in contact with the paper before it was excited, would cause similar spots. Your bath is of a good strength, and evidently working very well. Use the kaolin for cleaning it if you find it most convenient. In making pyroxyline, 140° Fah. is a moderate temperature, 150° high, but it much depends on the strength of the acids whether you will obtain a good soluble pyroxyline or not. With very strong acids 160° is not too high a temperature. These things must always be considered in their relations to all the circumstances. With the oil of vitriol of commerce, and nitric acid sp. gr. 1·420 in equal proportions, and a temperature of 150° we have obtained pyroxyline which dissolved easily about eight grains to the ounce of two parts alcohol and one part ether. Be sure you have the right strength of acid, and the right temperature, and if there be any modification in one, make the requisite modification in the other.

James F.—The protacetate of iron gives a more vigorous negative than the protosulphate developer. It may be made by adding 12 grains of acetate of lead to 12 grains of protosulphite of iron, and filtering out the precipitate; or, by adding 6 grains of acetate of soda, instead of the 12 of lead. In the latter case no filtration is necessary. Acetic acid must be added as usual. It should be used as fresh as possible, as it is not a stable preparation.

B. F.—Use a central stop. It is a great convenience to have a set of Waterhouse diaphragms adapted to a lens.

Hypo.—No amount of washing will make a print permanent if it has been imperfectly fixed. New hypo, of about 20 per cent. is the safest fixing solution. From ten minutes, to a quarter of an hour, will generally be sufficient. Developed prints are generally considered more permanent than sun prints.

Positive.—Flatted crown glass generally answers perfectly well for positives on glass. We have had some alabastrine positives nearly four years, which have not changed or discoloured. Melainotype plates are enamelled iron plates; unless carefully varnished at the edges they will injure the bath.

Lady Bird.—Pyrogallic acid is not suited as a developing agent, where the plan of intensifying adopted by Mr. Lacy is used. The class of picture required is full of detail, but not intense; and this is most easily obtained by means of iron development. See first article in the present number. The staining of the glasses by the use of iron development to which you refer is a small matter, as where you succeed in getting a good negative, the chances are that you do not need to use the same glass again; and in any case the glasses are easily cleaned by the use of dilute nitric acid, after the action of iron.

Henry H.—Add to each of the positive baths of which you speak some new solution and filter carefully; and at least another drachm of acetic acid to the developing solution. Regarding your negative bath, you do not state whether it is acid or alkaline, but from the description it is probable a little acid will put it right. The addition of ether and alcohol to a new bath is a useless and foolish proceeding; it will acquire more of these than is desirable very soon. Be sure you filter your bath carefully after adding iodide of potassium, collodion, &c., to it. The only thing in that line that need be done to a new bath, is simply to leave a coated plate in it for a few hours. Spots and comets are more likely to proceed from the collodion than from other causes. For the process given in the article named, any bath in good working order, will answer, and the fixing may be either hypo or cyanide. See articles in present number.

J. C.—The chief advantage of a binocular stereo camera is, that in portraiture both the pictures are taken at the same time, shortening the sitting and obtaining the same expression; and for landscape, that moving figures may be taken, and the same light and shadow always secured in both the pictures. The necessity of cutting in two is a small matter compared with this. Taking the picture with the collodion side towards you would make no difference in that matter; as the relation of the pictures to each other would not be altered. Each picture wants turning round *on its own axis.* The application of a little oil or varnish or anything of that kind will improve a very coarse ground glass for focussing, but nothing will make it perfect. We should change it at once for a proper one. We once tried one for a few months, and finally had to replace it by one properly ground.

C. F. B.—Sends us a couple of very charming stereographs in which water is beautifully rendered. We should like to know the process used in producing the negatives. The printing and toning are also excellent.

Phos.—We cannot answer you at length, as your letter only arrived on the day we go to press. We may remark for your immediate guidance, that if you are working with a collodion such as you describe, that is, with 5 grains of pyroxyline to 2 ounces of solvent, you can scarcely hope to get good negatives. Try double the quantity, at least. We will enter more fully into your difficulties in our next

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 135.—April 5, 1861.

NEW METHOD OF INTENSIFYING.—PREVENTION OF CRACKED FILMS.

We stated last week, in referring to intensifying processes in which salts of mercury were employed, that we had some experiments in progress for overcoming a difficulty commonly met with in these processes; namely, the destruction of the film by the action of the solutions.

The first method to which we shall refer is unique, and consists in avoiding the use of solutions altogether. It will not, however, we apprehend, be extensively used, except by old Daguerrotypists, who will probably possess the appliances and the experience necessary to use them with facility. We refer to converting the film into a yellow iodide of mercury, by the *operation of vapours only*. To do this we have simply made use of our mercury box and iodine box, which were exhumed from a quantity of old Daguerreotype apparatus for the purpose. A thin collodion positive was placed in the mercury box, and the spirit lamp applied to heat it after remaining there some time, the plate was removed and placed over the iodine box, where it gradually acquired a rich bright yellow tint from the formation of iodide of mercury. The yellow tint thoroughly permeated the film and showed alike on both sides; by reflected light it was of a bright canary colour, and by transmitted light a deep orange approaching to red. Although considerable additional thickness of deposit was manifest, the image was transparent in its densest part, and the various gradations were most exquisitely marked, without the slightest tendency to fill up or ignore the finest half tone.

The condition of delicacy of gradation is thus admirably secured. by obtaining printing intensity by means of colour rather than accumulation and thickness of deposit. We have not had opportunity to repeat the experiment at any length; but we may state that we have not been so successful where we applied the vapour of iodine first, and followed with the mercury. The plate is rapidly coated with iodine, and some accession of intensity is gained, but the deposition of the mercurial vapour does not appear so perfect as when the first mentioned method is pursued. A picture which has been submitted to the action of a solution of bichloride of mercury, rapidly acquires the yellow tint when submitted to the fumes of iodine.

As we have said, we do not apprehend that this method will be adopted except by old Daguerreotypists, who will be glad to learn that they have such a power in reserve, and that they can once more utilize some of their cherished apparatus connected with their regretted, but defunct process.

Regarding the methods of preventing the destruction of the film in the processes of intensifying, it is important to ascertain in the first place the causes which operate in producing such destruction. There is no doubt but that the prolonged action of any solution, will, in certain conditions of the film, have a tendency to loosen it and cause it to crack and leave the plate; but this prolonged action, even of a destructive solution, will only have such an effect when the conditions favourable for destruction are present.

We believe the most fertile source of destroyed films is imperfect cleaning of the plate, or the coating with collodion when the glass is not thoroughly dry. Even with a collodion adhering most tenaciously to the glass, and without the action of any destructive solution, this cause will frequently result in cracked films. As an illustration we may mention an experiment we tried the other day; we took two stereoscopic negatives with a collodion which adhered well to the glass; one on a carefully cleaned and dried plate, the other on one which had been carelessly and imperfectly cleaned. The first was treated by almost every possible means of intensifying in succession, iron, pyrogallic acid and silver, solution of iodine, again pyrogallic acid and silver, bichloride of mercury, ammonia, again solution of iodine, and again bichloride of mercury, and finally cyanide of potassium. Of course the printing qualities of the negative were destroyed, but we were trying the power of endurance of the film. It had copious washings between each application, and was under treatment altogether about two hours. It dried finally without a crack, or the film so much as turning up at a corner. The second negative, on a dirty plate was simply intensified by means of bichloride of mercury and ammonia; on drying the film cracked in several places, and curled up like horn shavings, becoming as Mr. Hughes pertinently phrased it, "a thing of shreds and patches." To our own minds this was a tolerably conclusive experiment as to one cause—we believe the most common cause—of splitting of films. The collodion was a bromo-iodized collodion, which had been made and iodized twelve months, the formula for which we have more than once given.

Another very fertile cause of this trouble where mercury is used, arises from the fact that hydrochloric acid forms part of the solution, the formula which used to be universally given, was to make a saturated solution of bichloride of mercury in hydrochloric acid, and add a little of this to water. This acid will always have an actively destructive influence on the film, and it is altogether unnecessary. Bichloride of mercury will dissolve in sixteen parts of water; thirty grains to the ounce forming a saturated solution, which is stronger than is necessary for intensifying purposes. If the salt be powdered and hot water be used, the solution is easily made. Where it is desirable, however, the addition of hydrochlorate of ammonia materially aids the solution, and allows a much larger quantity of mercury to be dissolved, whilst it in no way interferes with its action on the film.

Clean and well dried plates, a collodion not too new or contractile, but adhering well to the glass, allowing the film to set well before immersion in the bath, and the avoidance of solutions containing powerful acids, are the means of avoiding destroyed films, whatever intensifying processes may be used, and the neglect of these means, the sure method of losing the films wherever it is possible.

In conclusion we call attention to a communication in another column, containing the method of intensifying used by Mr. Brothers of Manchester, who is well known as one of our first provincial portraitists. We can endorse Mr. Brothers' statement of the value of the method he gives, from having frequently used it with perfect success.

HALATION: WHAT IS IT?

The last meeting of the Photographic Society proved a rather unsatisfactory *seance*. The chief subject brought under the attention of the meeting was an elaborate paper on halation, its true cause and remedy. The cause was stated to be the action of light, which having passed through the film and glass, was reflected back again on to the film; and the remedy, black varnish. We have no intention of commenting on a paper which we have not before us; but we have no hesitation whatever in endorsing the opinion of Mr. Shadbolt, expressed at this meeting, that the phenomenon there described and accounted for, might be fogging or overaction of light produced by reflection, but was in no sense what is usually understood by halation.

It is important in all discussions to define terms, especially where, as in the brief conversational discussion of Tuesday night, three or four distinct phenomena were referred to as halation. There was, to commence with, this action of reflected light, secondly, that described by Mr. Shadbolt, as halation proper; next the effect produced by the diffraction, or diffusion of light passing through windows into interiors, then the radiation of light from some very bright or white object on to the circumjacent parts, such as that seen on the opening of a waistcoat, where there is a very large expanse of white shirt front; and lastly an effect with which we are not familiar, to which Mr. Malone referred, described as a dark line between a glossy coat and a dark background.

With regard to two of these effects we think the cause is very evident, and does not involve any very occult law. The effect produced in an interior by bright sunlight coming through the windows, may be seen on the ground glass, and therefore requires no explanation on chemical grounds. In some instances the radiation of light, from a bright and white object on to a neighbouring dark one, may be seen easily enough, and was an effect as common in daguerrotypes as it is in the collodion process, and cannot depend on the condition of bath or collodion. That which is known as halation proper was doubtless the effect described by Mr. Shadbolt as a line of increased reduction where a very dark and very light object are in immediate contact, such as the foliage of a tree, and the sky, the deposit being chiefly on the sky, into which it gradually blends.

We venture to offer a theory for this, in the truth of which we know we are supported by some good operators. The deposit which constitutes a photographic image is largely formed by the reduction of the free nitrate of silver on the film; there is as much free nitrate on the dark parts of the image as on the light parts, but a considerable portion of it is not needed at these points; and it cannot be reduced there. The immediate action of the developer on the parts where light has acted, is to reduce the free nitrate in contact with them; and the free nitrate on the dark parts, in immediate contact, which cannot be reduced, is swept by the developer on to the light parts, where, coming in contact with particles of silver in the act of reduction, it also becomes reduced, and in the greatest degree at the first point of contact with the light parts, and gradually less so; forming the effect which Mr. Shadbolt described. How far the sun being near the horizon, as stated by that gentleman, would effect this result, we do not know, nor are we familiar with the fact. The presence of organic matter in the bath to which he also referred, would materially we think aid in bringing about the effect described.

This explanation is consistent with our own experience, and that of many we know; we offer it as meeting the case in the absence of a better theory.

THE TANNIN PROCESS.

We referred last week to a method of using gum in connection with the tannin solution, which had been found successful in counteracting the tendency of the film to leave the prepared plate in the processes of developing, fixing, and washing. The formula used by the gentleman to whom we referred is as follows:—

Tannin	15 grains
Gum arabic	25 ,,
Citric acid	2 ,,
Water	1 ounce

This preparation is used instead of the simple solution of tannin, and has, we understand, a beneficial influence in the resulting negative. The gum seems to act by filling up the pores in the film, and thus to some extent preventing that contraction and expansion to which the tendency of the film to leave the plate is chiefly due. The developing solution more readily permeates the film after exposure, and the action is consequently much more rapid; and there is, moreover, a tendency to preserve the half tone of the picture.

Mr. Hardwich, in giving the details of the tannin process, suggests that gum, in the proportion of from fifteen to thirty grains to each ounce, may be added to the tannin solution, to assist in the expansion of the film on being wetted previous to exposure. We apprehend, however, that unless the previous tendency of the film to contract on drying had been, in the first instance, to some extent counteracted by the gum, its subsequent ready permeability by water, and expansion, would only increase the tendency to leave the plate.

Since writing the above, we have had another communication from Major Russell, which will be found amongst our correspondence. His experience with gum, it would appear, does not bear out the opinion of the gentlemen to whom we have referred. We, of course, defer largely to the opinion of Major Russell, based as it is upon practice with his process, extending over a greater period of time than it has been used by any other person; extended experience in various hands, will be, however, necessary to decide the question absolutely.

Scientific Gossip.

The spectrum researches seem to be absorbing nearly all the attention of scientific circles. The more the subject is investigated the more powerful and searching a means of chemical analysis does it appear to be; a striking illustration of this has just come to our knowledge in the discovery by Mr. Crookes of a new elementary body by its means. A residue left behind in the purification of some selenium, being suspected, from its reactions, to contain a portion of the very rare element tellurium, was, after remaining unnoticed for ten years, lately submitted to chemical analysis, for the purpose of preparing the tellurium from it. The ordinary chemical tests were in vain tried upon it. *Something* was evidently there which possessed well marked reactions, but it was not tellurium or selenium; and as a last resource the method of spectrum analysis was used. A portion of the residue introduced into the gas flame of the apparatus gave abundant evidence of selenium, but as the alternate light and dark bands due to this element became fainter, and the observer was expecting the appearance of the somewhat similar but closer bands of tellurium, suddenly a *bright green line* flashed into view and quickly disappeared. An isolated green line in this portion of the spectrum was hitherto unknown. Mr. Crookes had become intimately acquainted with the appearance of most of the artificial spectra during eight or nine years investigation, and having never met with an appearance like this before, at once pronounced it to be due to a new element. Observing a line is one thing, isolating its cause is another. The apparatus used was capable of showing unmistakable lines when the producing element was not present in larger quantity than the millionth part of a grain; and the residue that showed this green line being itself difficult to be obtained, it became doubtful if ordinary test-tube chemistry would be capable of separating the interfering body from the mass of extraneous matter. Fortunately, however, our experimentalist met with more success than might have been anticipated. A certain quantity of the substance which caused the appearance of the green line has been really isolated and its properties examined, which leave no doubt that it is a real addition to the family of elementary bodies. In the purest state in which it has at present been obtained, it communicates as definite a reaction to the flame as soda. The smallest trace introduced into the burner of the spectrum apparatus giving rise to a brilliant green line perfectly sharp and well defined upon a black ground, and almost rivalling the sodium line in brilliancy. It is not, however, very lasting: owing to its volatility, which is almost at great as that of selenium, a portion introduced at once into a flame merely shows the line as a brilliant flash, remaining only a fraction of a second; but if it be introduced into the flame gradually, the line continues present for a much longer time. Several of its chemical reactions have been made out. These alone leave no doubt as to its being a new element, but in order to make assurance doubly sure, Mr. Crookes has subjected to rigorous scrutiny, in his spectrum apparatus, *every known element*, and has recorded that not one of them, although many give beautiful spectra, produces an isolated green line any where near the position of the new line. In fact there is not one element except sodium which gives a spectrum equalling it in simplicity. There still may be urged, against the supposition that this is a new element, the possibility of its being a compound of two or more known elements, or an allotropic condition of one of them; a moment's thought will, however, show that neither of these hypotheses are tenable. They would in reality prove what they are raised to oppose, for nothing less could follow than a veritable transmutation of one body into another, and a consequent annihilation of all the groundwork upon which modern science is based. If an element can be so changed as to have the spectrum of its incandescent vapour (which is *par excellence* an elementary property) altered to an appearance totally unlike that given by its former self, it must have been changed into something which it originally was not; and this, in the present position of science, is an absurdity.

In the annual exhibition of inventions just opened at the rooms of the Society of Arts there are one or two things exhibited of interest to photographers. The first is a stereotrope or stereoscopic thaumatrope, exhibited by W. T. Shaw. This instrument consists in the application of the principle of the stereoscope to that class of instruments variously termed thaumatropes, phenakistoscopes, phantoscopes, &c., which depend for their results on "persistence of vision." In these instruments, as is well known, an object represented on a revolving disc in the various positions it assumes in performing a given evolution is seen to execute the movement so delineated; in the stereoscope the effect of solidity is superadded, so that the object is perceived as if in motion, and with an appearance of relief as in nature. Pictures for this instrument may be varied infinitely, the only limit being the skill and ingenuity of the photographer; and it is peculiarly fitted for the representation of all kinds of machinery in motion.

A useful instrument, for the working photographer, is likewise exhibited by J. Moule. It is called the self-acting photographic washing apparatus and chemical filter, and is intended for washing photographic prints and collecting silver from the washings. It consists of a large upright box, the top of which is formed into a trough for washing the photographic prints in. From this trough the water charged with silver is allowed to overflow through a wastepipe into what the inventor terms a "float chamber," immediately beneath. When this chamber is filled to a certain height, the float begins to rise, and at the same time it lifts a valve attached to its upper surface, which when at rest accurately fits a conical hole in the bottom of the washing trough. This is in consequence emptied of its washings, which in the first place pass into the float chamber, and ultimately (by means of an aperture in its upper part and a syphon tube covered by the float) into a third chamber called the mixing chamber. As soon as a sufficient amount of liquid has accumulated in this third chamber to reach the top of a tube, which reaches nearly to its upper part, it passes down it into a fourth, the salting chamber, and is there saturated with common salt by means of crystals of that salt, which are placed in a perforated compartment at the upper part of the salting chamber. A little more accumulation of washings from the first and second chambers causes the liquid to rise to the level of the bend of a syphon in the mixing chamber, the action of this is thereby started, a flush takes place from the salting chamber, and a part of its contents returns charged with salt, and the whole is then carried over into a fifth chamber, called the precipitating chamber, by the action of the aforesaid syphon; here the chloride of silver formed settles to the bottom and accumulates, and the supernatant liquid is carried off after passing through a filter. This filter is formed of a perforated tube filled with cotton-wool and zinc-filings, so arranged that any particles of unprecipitated silver salts that may have escaped the first attack may be reduced by the zinc, and retained in the interstices of the wool. In this large precipitating chamber is fixed an air tube, which, however, may be connected with the developing sink, so that its drainings may be at once carried into the precipitating chamber. There is also a capped tube about one-fourth of the height of the chamber from the bottom, for drawing off the supernatant liquid, when it is wished to remove the precipitated chloride of silver through a stoppered aperture placed at the bottom of the chamber. All the parts exposed to the action of the solution, are constructed of a material that is impervious to water and the chemical action of acids, &c., and therefore not likely to readily get out of order. The frequency of the change of water in the washing trough is regulated for any given interval of time by the adjustment of the supply by means of a tap. The salting chamber once charged with a saturated solution of salt, and rock salt placed in the perforated compartment over it, is calculated to be sufficient to precipitate fifty ounces of silver, and beyond keeping this charged with salt, no other attention is requisite. The washing trough may be used as a sink where developings are carried on, by which a large amount of silver can be saved, which is at present lost.

POSITIVE PRINTING.

Mr. Maxwell Lyte has communicated to the *Moniteur de la Photographie* some practical remarks on positive printing on albumenized paper. Passing over the details of the method of albumenizing paper, which may be found in every treatise on photography, he proceeds to remark that it is a very great error to add acetic acid to the albumen, for, since the latter is alkaline, the addition of acetic acid produces an acetate, with the subsequent formation of acetate of silver in the nitrate bath. This salt being very unstable, the paper containing it turns rapidly brown when kept. The proportion of salt added to the albumen must not exceed two per cent. The operation of albumenizing the paper should be made in a dry place in dry weather, and the paper itself should be dried before being albumenized. The brilliancy of the proofs depends on this condition. The paper should be floated on the albumen not more than two minutes, for if it be allowed to remain longer, the albumen is apt to dry streaky, and will not have the fine texture desired. In fact, if the albumen does not dry quickly, but has time to penetrate the paper, the proofs will appear dull and faded. The best paper is that called *papier Saxe*, which is made in Germany; but some French papers are equal to it in quality, and are not so dear; the real *papier Saxe* costs 80 francs the ream, while the French is not more than half that price. The paper should be kept some time before being albumenized, by this precaution the metallic spots disappear by oxidation. After being albumenized it cannot be employed too soon, and it should be kept in a dry place. But in spite of every precaution, albumenized paper always becomes deteriorated in the course of six months. This arises from the salt in the albumen, which at first on the surface, afterwards sinks into the paper, so that the sensitive compound is formed in its tissue. When the paper is nitrated the result is, that after being printed, the image not being on the surface of the paper loses much of its brilliancy.

To sensitize the paper, dissolve five or six drachms of nitrate of silver in every thirty drachms of distilled water. Put the solution in a flat dish, and float the paper, carefully avoiding bubbles, for at least four minutes; it is then lifted and drained. The bath must be kept of uniform strength by the addition of a suitable quantity of a stronger solution of nitrate. After a certain time the bath becomes thick and coloured. Many methods have been proposed for remedying this inconvenience, such as coagulation by heat, which is not efficacious; or mixing with kaolin, and filtering, which is effectual, but expensive. The objection to the addition of citric acid is, that it renders the bath very acid, and that the paper sensitized upon it is very slow in receiving an impression, by the action of light, and also acquires a disagreeable red hue. The method proposed by Messrs. Davanne and Girard, which consists in adding a little of a solution of common salt to the discoloured nitrate bath, and afterwards filtering, is the best. Or the following modification may be tried:—Make a mixture of crystallized phosphate of soda 110 parts, with crystallized carbonate of soda 40 parts. Take of this compound, 70 parts, and dissolve it in 1000 parts of water. About 50 grains of this solution added to a pint of the bath is sufficient to deprive it of its dark colour, and render it neutral.

(*To be continued.*)

ON MANIPULATING WET COLLODION PLATES IN THE FIELD

BY VERNON HEATH.*

Let me in the first place explain the reason why I am induced to bring this subject before you. I have frequently noticed that, at meetings of various photographic societies, papers have been read on this subject, but I have always remarked that the operator merely described the manipulation of stereoscopic plates, or, at all events, of plates of small size: in several instances indeed, I have noticed that the size of the plate was not even mentioned. In fact, I have no hesitation in saying that, in nearly every case where papers have been read before societies upon manipulating in the field, either with the old or any of the new processes, the operator's experience was limited to small plates.

I recollect once reading a paper which had been produced before a provincial meeting, in which the author commenced by condemning every dark tent or box in use, and then explained a contrivance of his own which he carried in his coat pocket; but he nowhere described the size of the picture he worked; and it was only by observing that in one sentence he spoke of the stereoscopic effect of his pictures, and the angle at which they were taken, that I was able to determine the size of the negative he obtained. Now, I believe that the condemnation of tents and dark boxes by those whose operations are limited to small-size plates are as gratuitous as unnecessary, for it requires but the exercise of a very little ingenuity to work small plates without any such contrivance at all.

I once knew a zealous follower of the art who worked the collodion process thus:—He fitted his camera in his hat, punched out a piece of the front of the hat the size of the lens, which piece he refitted and attached a string to, and when working used it as the cap of his lens. In one breast pocket of his coat he had his bath, and in another his developing bath, fitted with yellow glass; and with such means he succeeded in obtaining pictures.

But the dark tent and chamber are, however, necessary for those who work plates of ordinary landscape size, and as I believe that the wet process is superior to any of the dry processes, where really artistic and truly satisfactory results are desired, I will now state my own experience and mode of manipulating that process, venturing to believe that it might be in some measure acceptable to the society if I described the exact means which enabled me to procure the negatives from which my pictures now in the Exhibitions are printed, and one of which this society has done me the honour to select as its presentation picture—the London Photographic Society having selected three for a similar purpose. I shall refer chiefly to my photographic visit to Endsleigh, the seat of his Grace the Duke of Bedford, in Devonshire.

Probably the points of peculiarity in my manipulation, and those most worthy of your attention, are—First, my method of working Smartt's tent; second, what would generally be considered the *over-exposure* of my negatives; third, my method of developing; and fourth, the deferring of fixing till the end of the day, or to some other convenient time.

First, then, as to the apparatus.—My negatives are all on 12 by 10 plates, and, with the exception of one (which was previously mentioned in this room, and which was taken with a Ross's 8½ by 6½ orthographic lens) were all taken with a Grubb's C lens—a lens which is intended to cover merely 10 by 8, and I think it will be allowed that the definition, even to the margin, is all that can be desired. At this point I may be permitted to observe that I believe the landscape lens *par excellence* is that known as the single lens; and that, for this purpose, it is superior to all the new lenses, whether orthoscopic, orthographic, or triplet. I do not mean, in speaking of Mr. Grubb's lens, to disparage the landscape lenses of Mr. Ross, Mr. Dallmeyer, or any other maker of eminence; I am merely mentioning the fact that my pictures were taken with a Grubb's lens, and that I think as highly of it as possible for landscape work. My camera is a folding one, and, although somewhat heavier, I consider it superior to that known as Captain Fowke's, or Mr. Kinnear's, inasmuch as it is firmer and more rigid. The tent which is before you is that known as Smartt's, and I must say that, for field work, I know nothing so efficient and convenient. I have arranged in it some special fittings and contrivances of my own, to which I will refer presently. I used Ponting's collodion only, and a bath made after his formula.

Now for the manipulation.—In the first place I am most scrupulously careful and particular in every portion of the process, and I think it impossible to photograph properly without being so. In cleaning my glasses, I use nothing but alcohol and tripoli, applied with a tuft of wool, and then thoroughly removed with a linen cloth. I then pour on a few drops of alcohol, which I rub off with a clean linen cloth, and finally polish with a leather. To one side I give a little more attention than to the other, and I stow the clean plates away in pairs, placing the two well-polished sides together.

Then as to the manipulation in the tent.—The general arrangements of Smartt's tent are now so well known that it is only necessary that I should point out the contrivances I have had fitted to it. For instance, a water bottle is hung over the table, which I can work with one hand, and the negative bath is suspended from the front of the table, as you see. Over one part of the table, and attached to the rods of the frame, I have contrived a shelf, where the *chassée* of the camera is placed; this, it will be seen, is a very useful contrivance. I coat my plate in the tent, after having first carefully closed the opening. When the plate has been in the bath the requisite time, I allow it to drain for a few seconds, and then remove it to another little ledge I have contrived, and allow the draining to complete: it is now ready for the *chassée*. I mention this with some minuteness, because I am quite sure that one of the most prolific sources of stains upon negatives is due to the plate not being sufficiently drained before it is placed in the *chassée*. I not only drain it thoroughly, but I put strips of blotting-paper along the top and bottom of the plate. The plate is now supposed to be in a proper state to go into the *chassée* of the camera.

With regard to the exposure in the camera, I believe that the most artistic effects are produced by what is termed *over-exposure*—a term which ought no longer to be allowed if its results are superior to those from negatives exposed a less time. Excepting, of course, burnt-up pictures, I do not think there is any such thing as *oxer-exposure* in landscape photography.

* Read at a meeting of the Blackheath Photographic Society, March 18, 1861.

It must not be supposed, however, that I mean by over-exposure exposing for a great length of time. The average exposure of my negatives, in varying but good light, was about thirty seconds, using a lens, it should be remembered, of fifteen-inches focal length. What is usually understood by the term *over-exposure*, the several negatives I now produce will illustrate. It will be perceived there is a want of that complete brilliancy which negatives, believed to have been exposed a proper time, generally exhibit. If they are viewed by transmitted light a slight redness will be perceived, and this is usually supposed to be a sign of *over-exposure*.

The effect which I believe is produced by what is erroneously called over-exposure, or at all events by negatives in the condition of these, is a greater gradation of tone and softness of effect, and the different planes of the subject are brought out in a much more beautiful manner. I think that when a negative appears very brilliant there is generally a flatness of effect. I lay some stress upon this point, as I really believe it to be important, and I think that if more attention is paid to it better and more artistic effects will be produced.

Now I believe that my method of development is peculiar —at all events I think that that distinctiveness of character which is stated to belong to my pictures is, in a great degree, due to the nature of the development. I prepare sufficient developer for a day's work, of the following proportions:—Eight grains pyrogallic acid, eight ounces of water, one drachm of glacial acetic acid, and one drachm of alcohol. This is about the strength that a pyrogallic developer is generally used; but though I thus prepare it, I do not use it of this strength. I have a bottle of distilled water in my tent, and into one of my developing cups I pour just sufficient to cover the plate, —say two ounces.

Being now ready to develope, I carefully close the tent, and, having previously placed the *chassée* on its ledge, I remove the plate with the pneumatic developing holder, and pour over it very carefully the measure of distilled water. I allow this to flow over and remain on the plate for a few seconds, and I thus take up a large portion of the free nitrate of silver. I then pour the water back into the developing cup, and add to it about a drachm of the pyrogallic solution, so that instead of commencing my development with a one-grain solution of pyrogallic, I have merely taken a drachm of a one-grain solution to two ounces of water. This is a very weak developer, and of course the action of development is much retarded—the picture coming out very faintly and gradually. It is, therefore, very manageable and pleasant, and in hot weather will be found most advantageous; and, what is of great importance, I obtain the details in the shadows to an extent I never succeed in getting with an active developer.

When I am satisfied with the amount and effect of details produced (the negative at this stage being faint, and of an intensely red colour), I slightly wash the plate and complete the development with the one-grain solution of pyrogallic, to which, if it becomes necessary, I add a few drops of silver, —but, if possible, it is better to do without the latter. I then wash sufficiently to remove the developer, and at once place the negative away in a box I have had made for the purpose, in which the grooves are of such a form that they cannot injure the edges. I put a pad of wet blotting paper at the top and another at the bottom of the box, and the negatives are thus kept sufficiently damp until the end of the day, or even until the next day, so that I am enabled, without risk, to fix them. I do not fix in the field unless circumstances compel me; and to those who use the wet process this is an immense advantage, as it saves time that is valuable, while the necessity of having a large supply of water is avoided.

I may mention that if, by any chance, the edges of the film are injured previous to fixing, so that there would be a risk of losing the film during the fixing and washing, I first of all dry the negative thoroughly, and then with a camel-hair brush and the ordinary spirit varnish, I paint round the edges and damaged places, and when dry and hard I float water upon the negative until the film is saturated. I then fix and wash in the ordinary manner. By adopting these means I have never lost a negative; but I very seldom have one damaged so as to render this treatment necessary.

To complete my remarks upon the use of the tent, I ought to explain that there are cords furnished with it, which, whether there is wind or not, I always make a practice of securing the tent with previous to using it. No doubt a high wind would blow it over but for these cords; it is, however, secure enough with them, and as the cords are sold with, and are therefore a portion of the tent, I should just as soon think of putting up the tent without the cover as without them.

The actual chemicals and other things required for use in the tent are contained in a field-box of a very convenient and portable form; and, as I always place it in exactly the same position underneath the table of the tent, I am able to find whatever I want without any difficulty. In my field-box I carry a spirit lamp, which I find very useful for drying plates from condensed vapour, which forms upon them during such a season as that of last year.

I have now said all that I at present desire to state upon this subject; and I shall feel obliged if you, sir, or any member of the society, will make any observations you think fit upon the remarks I have made. I may say that I have a passion for the art, and that whatever falls in my way calculated to forward it, I feel the greatest pleasure and gratification in communicating.

In conclusion, let me say that, if everybody would try to find out how little could be done with it in the field, there would not be the objections against the wet process we hear of at present. I think that those who prepare plates for any of the preservative processes really in the end take a great deal more trouble than is required for the wet process; there is the ordinary preparation of the plates in the first instance, the washings afterwards, then the application of the preservative, and at last the chance that the plates may not turn out good, for a very large per centage certainly do not.

[During the course of his remarks, Mr. Heath produced a great number of illustrative negatives and prints. He also put up his dark tent, and exhibited the various ingenious contrivances he referred to.]

THE RESIN PROCESS.

BY J. GLOVER.*

The ground on which I propose to take my stand is, first of all, to demonstrate as briefly as possible its *simplicity*, and then to meet the charges which have from time to time appeared against the "resin," or more appropriately the "Despratz" process.

In urging the first point for consideration, allow me to ask what formula can entail less complexity than one in which the sensitive surface requires *no application of a preservative*, but simply washing with an indefinite quantity of spring water—that succeeds with an acid silver bath—and that developes with all the rapidity of moist plates? How many photographers, worthy of the name, are there who, after arriving at excellence little short of perfection in wet collodion, shrink from the difficulties which have hitherto attended the manipulation of dry plates, and who, from motives not altogether pecuniary, refused to adopt those prepared by the agency of others? Such individuals would hail with the highest degree of satisfaction a dry process combining simplicity with a tolerable degree of sensitiveness. The writer affirms—and it is the experience of every one who has followed out the process under consideration—that no other one approaches so nearly to the manipulation of wet collodion; for, I ask, in what does the difference consist but in copious washing and the usual precautions in drying?

* Read at a meeting of the North London Photographic Association, March 27, 1861.

I can state with the greatest assurance that any good negative operator can produce, with suitable materials, a seccessful dry resin plate. So much for simplicity.

The *objections*, real and imaginary, which have been urged against the process, I have no doubt, have deterred many from giving it a fair trial. They are, however, happily overcome without difficulty. The foremost—and which, if well founded, would have proved altogether fatal to its adoption, and stamped it as unsound in principle—is the alleged deterioration of the bath from the introduction of such a carbonaceous substance as resin. This, however, as far as I can learn, was only hinted at theoretically. Far from being sound doctrine, I find practically that, in the homœopathic doses which are recommended, it is perfectly inert as regards any action upon the silver solution. After using a bath for a whole season, the plates last immersed in it were, if anything, more sensitive than those prepared at the commencement, and without any of the effects attendant upon an excess of organic matter in the solution. This is not alone my individual experience: it is borne out by several of my friends. It rests with those interested in the chemistry of our art to determine what is the effect upon the film itself. Irrespective of the mechanical action, I would suggest—Is there not some chemical change—viz., the precipitation of *pinate of silver*—which partially accounts for the preservation of the collodion in the sensitive state, as well as the amount of that sensitiveness?

The next two, and by far the most general, objections, are the *liability* of *the film to become detached from the glass* during developement or subsequent washing, and the *existence* of *small circular insensitive spots* which remain transparent after prolonged action of the developer.

If a suitable collodion, with the minimum quantity of resin (say a quarter of a grain to the ounce) be employed, these defects are entirely obviated. Supposing a sample of collodion, suitable in every other respect, should show a tendency to leave the plate, if, prior to moistening, a camel-hair pencil dipped in benzole varnish, be passed round the edge, an otherwise tender film will remain intact. The collodion I recommend is one composed of about two-thirds cotton and one-third paper pyroxyline (both produced from acids at medium temperatures), iodised with cadmium salts, used as soon as in good working order for wet plates, and that does not give, under such circumstances, an intense image. It should stand two or three days after the addition of the resin, and be decanted for use. Such a collodion, sensitised in a forty-grain silver bath, containing from three to four minims of glacial acetic acid to the ounce, will endure the thorough washing it is then to undergo—remembering it is the last traces of free nitrate that retard the sensitiveness of dry plates. I recommend *spring* water, so as to ensure, by chemical agency, this desideratum, and is much safer than adding a chloride to pure water, it only remains to dry spontaneously, carefully excluding dust, without confining in a moist atmosphere.

The third difficulty is the *splitting up of the film*, on drying the finished negative. The cause is obvious—the employment of too contractile a collodion; nevertheless, should it prove otherwise suitable, a certain remedy has been suggested by my worthy friend Mr. Corey, and consists in flooding the plate with dilute albumen previous to the final drying.

The fourth and final difficulty with which we have to contend is *want of density*. This is not so much a characteristic of the process, but, as previously stated, the kind of collodion most suitable is prone to this defect (if such a term is rightly applied); for I find no difficulty in obtaining the necessary amount of intensity, with absence of hardness, by using a strong developer—never less than three grains of pyrogallic acid to the ounce of water.

I would urge at this point the question—Is not this seeming drawback rather to be viewed in the light of an acquisition? In most dry processes we have complaints of the opposite tendency, so much so, indeed, that it has been a by-word among the votaries of the wet process, who, on criticising one of those pictures displaying stronger contrasts than ever existed in nature, naturally exclaim—"Surely this is from a dry plate! is it 'gelatine' or 'oxymel?'"

Having thus hastily glanced at the difficulties, allow me, in conclusion, to give my experience as to the comparative sensibility of the various dry processes, to which I have given a fair trial.

Taking "Resin" as the standard, which I find to be the most sensitive of any by a published formula	1
"Fothergill," with chlorided albumen ...	$1\frac{1}{2}$
Do. original formula	2
"McNair"	2
"Oxymel," on unwashed collodion	3
"Gelatine" (Patent Dry Plate Co.)... ...	4

The above were all treated the same as regards their developement.

THE PANORAMIC LENS.

BY PROFESSOR DELAMOTTE.

An interesting letter on the subject of the panoramic lens and its capabilities has been addressed by Professor Delamotte to the *Journal of the Society*. As his judgment as an artist and practical photographer of known ability possesses weight, we make the following extract from his letter:—

There are three points on which a practical photographer must convince himself respecting the lens. The first is to ascertain whether the lens gives uniformly good definition at the sides as well as the centre of the picture. The second, to ascertain whether it works free from flare and fog, and with equality of illumination. The third, to ascertain how much angle the cylindrical picture will include vertically, as well as horizontally.

On these three points I will simply state my conviction, founded upon what I have actually seen. As regards definition, I am not one of those, as you well know, who think there is anything charming or artistic in bad focus. I think it has been fully proved by photography that the finest possible definition, or focus, is compatible with the highest artistic excellence; and I hold, moreover, that a lens which does not give good focus will not do, and is to be condemned. But I am satisfied with the panoramic lens on the score of good definition.

In one of the negatives, the central definition is equal to anything I have ever seen; and, in another, good average definition is extended over the whole picture. The lenses with which these pictures were taken have not been made of the best glass, or with suitable mechanical appliances, and yet the results are already good enough to satisfy one, even if nothing better should be obtained when the apparatus is more accurately made.

As regards fog and flare;—The common lenses are sheltered by a tube or hood, but the panoramic lens projects beyond the mounting. Is this likely to fog the picture? The question can easily be answered by an appeal to experiment. All Mr. Sutton's panoramic negatives, that I have seen, are clean and dense, like any other good negatives, and exhibit no indications of fog or dark spots, or inequality of illumination. They have been fully exposed, and in one case with the shadows thrown *towards* the lens, and yet they are as perfectly free from fog as any other good negatives. This settles the question of fog.

The angle included in the vertical direction seems to be about the same as with the ordinary lenses. The foregrounds are in every case perfectly in focus, to a *great* depth below the horizontal line.

The negatives to which I allude have been taken with a panoramic lens $6\frac{1}{2}$ in. focus, measured from the centre, and $\frac{1}{4}$ in. stop; and Mr. Sutton informs me that the exposure was generally about a minute, in good diffused light. With a common view-lens of the same focus and stop, the exposure was rather longer. The reason is, that the panoramic lens admits a much larger pencil upon the front glass than is determined by the size of the stop.

As an artist, I assure you I feel the greatest interest in the new lens. I am enthusiastic about it, and expect great things from it. It seems to me to be exactly what was wanted. When I go out to make sketches, I find, as a rule, that my sketch includes nearly twice as much subject as a common camera will take in; and nothing has been so mystifying to me, in my photographic practice out-of-doors, as to be unable to include all that I require upon the ground glass. This circumstance has greatly damped my ardour in photographic view-taking; but Mr. Sutton's new lens gives me all that I wanted, and opens a new field to me. I wish I could make your readers feel this. The panoramic lens is really and truly what photographic *artists* most want. I consider it a grand invention. One is not obliged to take panoramic pictures with it on *all* occasions; one may be content, perhaps in the majority of cases with 60° or 70°; but to remain content with the 30° or 40° which the common lenses give is to me impossible.

Mr. Ross speaks with confidence, and I believe I may say with enthusiasm, of what he expects this new lens to accomplish. He is arranging costly mechanical appliances for its especial manufacture; and before many weeks I hope to be able to inform you that I have actually tried one of these lenses made by him, and produce satisfactory results with it.

Proceedings of Societies.

North London Photographic Association.

The annual meeting of this Association was held on the evening of Wednesday, the 27th ult. Mr. G. Shadbolt in the chair.

After the minutes of the preceding meeting had been read,

The Chairman read a letter from Mr. John Cramb, of Glasgow, relating to his articles on the hydrometer bath tester.

"67, *West Nile Street, Glasgow, March* 23, 1861.

"Dear Sir,—I am anxious to offer a few words of explanation through you to the members of the North London Photographic Association, regarding the hydrometer silver meter question. It would be difficult for me to risk entering at any length on that subject, without endangering further my own peace of mind and that of those for whom I entertain the highest respect, notwithstanding that we have taken a different view of a matter which has, no doubt, two sides. I merely wish in this note to disclaim distinctly any *intention* to give offence, or any *expectation* that anything I was doing was calculated to do so; and I feel no difficulty in expressing the most sincere regret that anything I have written should have had an effect I never contemplated.

"On the treatment I have received I make no further remark than that I leave it to the gentlemen who have animadverted on *me* and my conduct to do as to them seems just and honourable.

"My views on the merits—as a lawyer would phrase it—are unchanged.

"You will perhaps be kind enough to read this at your first meeting. By so doing, you will oblige your most obedient and humble servant, John Cramb."

"J. Barnett, Esq., Hon.-Sec.,
"North London Photographic Association."

The Chairman remarked that, after a person who had done wrong had expressed his regret, nothing more remained but to let the matter drop.

The Chairman then read a paper, entitled, "A Plea for the Resin Process," by Mr. J. Glover, of Liverpool. Some extracts will be found in another page. A series of negatives illustrative of various points in connection with the process were exhibited; the chief defect illustrated was the spottiness and tenderness of film incident upon the addition of too much resin.

Mr. Dawson remarked that the negatives generally seemed a little hard from under-exposure.

Mr. G. Wharton Simpson said he had some years ago, in the course of some experiments on the action of kinds of organic matter in collodion, added Canada balsam and Venice turpentine in various proportions. His experiments were confined to the wet process, but he had not observed any of the disadvantages sometimes attributed to the use of resin. With the addition of various proportions up to about two grains per ounce, he had not observed any difference beyond the film adhering to the glass with a little more tenacity. About two grains per ounce and upwards began to cause spots, which seemed the nuclei of more intense reduction of silver.

Mr. Hill said the chief danger he should have apprehended was injury to the nitrate bath.

Mr. Simpson said he had excited some scores of plates in the nitrate bath he was regularly working, and had never perceived the slightest injurious result.

The Chairman.—When the Despratz process was first published he had tried the addition of chloroform varnish to collodion; but the results were unsatisfactory, and the film was made very pulverulent and rotten. As analogous in character he had also tried the addition of camphor, but the result was still unsatisfactory.

Mr. Hill had tried the use of amber varnish; and had not found any bad results, but he had not carried his experiments to any length.

Mr. Simpson had tried the use of camphor. It had the effect of making the film powdery, and caused an opaque bloom on the shadows.

The Chairman then read a communication from Dr. Maddox, on a curious effect in developing a wet collodion plate, in which the image appeared partly negative and partly a transmitted positive.

A conversation on the subject followed, in which Messrs. Dawson, Hill, Moens, Simpson, Foxlee, the Chairman, and others, took part. It was stated that the circumstance was not an uncommon one, and might be produced by a variety of causes, such as a splash of hypo getting mixed with the developer, the action of light whilst developing, prolonged development with iron followed by pyrogallic acid, especially when the bath was old, and other causes.

Mr. George Dawson then read an interesting paper in continuation of his analytical experiments on silver baths, in which he had had an opportunity of examining some of the silver baths which had been tested in Glasgow. In regard to two of these he discovered some very remarkable facts, one contained a quantity of nitrate of potash altogether inexplicable, except on the hypothesis of the action addition of that salt, and another labelled an "old collodion bath" which had no trace whatever of ever having been used for such a purpose. The paper is too important and interesting in its entirety to admit of condensation or abstract, we hope, therefore, to give it at length in an early number.

The annual report and balance-sheet were then read, from which it appeared that the Society was prospering, and had a balance in hand of £11 10s. 6d.

Mr. Dawson moved and Mr. Simpson seconded the adoption of the report, which was carried.

The President, Vice-President, Treasurer and Secretary were then, on the motion of Mr. Dawson, re-elected.

On the motion of Mr. Hughes, the rule enacting that the committee consist of six members was modified, to make the committee consist of eight members.

The following gentlemen were then elected as members of the committe for the ensuing year:—Messrs. T. A. Barber, F. Bedford, G. Dawson, C. Jabez Hughes, G. R. Mainwaring, C. J. Moens, W. Shave, and G. Wharton Simpson.

In the course of the evening the following gentlemen were elected members of the society:—Messrs. H. Morton, S. Evershed, J. M. Mackie, John Louch, S. Mason, A. H. Bateman, R. Gordon, R. Ramsay, Bradshaw, Gillivray, Joyce, B. Smith, Dickinson, Denison.

The usual votes of thanks terminated the proceedings.

Blackheath Photographic Society.

The ordinary meeting of this Society was held on Monday, the 18th inst., at the Golf Club House, Blackheath. Charles Heisch, F.C.S., in the chair.

The minutes of the last meeting were read and confirmed.

The Chairman then called on Mr. Vernon Heath to read a paper on "Manipulating Wet Collodion in the Field."

In the course of his paper Mr. Heath exhibited his tent and the various contrivances he had employed to facilitate manipulation.

The Chairman then said he felt sure all present must feel much indebted to Mr. Heath for his paper—many points in it were most valuable. He could himself vouch for the benefit of a weak developer, which he always employed, more especially for dry plates, though he had never carried it to the extent recommended by Mr. Heath for wet ones. He had no doubt the plan of pouring water over the plate before development would also prove valuable as equalizing the action of the developer. One statement of Mr. Heath's surprised him not a little, this was that it was possible to dry the plates before fixing, even after varnishing the edges—he should have expected to see the film crack all over.

Mr. Heath said if all the injured parts of the film were varnished so as to prevent the fixing liquid getting under it, he had never found it crack.

The Chairman said much would depend on the quality of the collodion, if it were contractile it would of course be much more liable to crack. Some very good collodions were apt to crack at the edges of the plate even in the process of drying.

Mr. Heath said this might generally be prevented by completely freeing the film from the ground edges of the plate as soon as the film got sufficiently dry by wiping round the edge with a damp cloth, which permitted it to contract evenly. This plan had also the advantage of making the plates look very neat.

The Chairman said Mr. Spiller had mentioned to him that he had some unvarnished plates, the film on which, after keeping some months, had suddenly cracked all to pieces and come off the plate.

Mr. Heath said he had seen some which had cracked after varnishing, but never before; none of his own plates had ever cracked, varnished or unvarnished.

In answer to a question by Mr. Glaisher—

Mr. Heath said all the negatives he had taken in the field were fixed with hyposulphite of soda, but he had lately tried fixing with cyanide of potassium on some plates developed with iron, which had answered very well.

The Chairman said he thought plates developed with iron stood the action of cyanide of potassium better than those developed with pyrogallic acid, the latter being apt to lose some of the delicate half tone.

Mr. Heath then said he had been experimenting lately in portraiture with various collodions, and had found a collodion made by Mr. Thomas, and iodized with magnesium, give peculiarly beautiful half tones, which he had not seen with other collodions.

The Chairman said he believed this was due much more to the fact that the collodion in question contained a large amount of bromide, than to the fact of its being iodized with magnesia salt. He would ask Mr. Heath if he found collodion, iodized with magnesium, kept as well as had been stated by some people.

Mr. Heath said it kept pretty well, but not like that iodized with cadmium. It lost sensibility after five or six weeks. All the pictures he had produced were taken on collodion iodized only a day or two.

The Chairman said he had tried magnesia salt, but did not find the collodion keep better than any other containing the same quantity of bromide. Even when iodized with ammonia salt, collodion would keep well for two months if it contained a good quantity of bromide.

Mr. Heath presented the society with a portrait of the President, taken on the collodion he had mentioned.

Mr. Glaisher proposed and Mr. Hardy seconded a vote of thanks to Mr. Heath, for his paper and the portrait, which was carried unanimously; and the meeting adjourned.

London Photographic Society.

The usual monthly meeting was held on Tuesday evening, the 2nd instant. P. Le Neve Foster in the chair.

After the minutes of the previous meeting had been read by the Secretary,

The Chairman announced, that M. Claudet had been elected a member of the council, in the place of Mr. Walter Hawkins, who had declined to act in the council after his election at a recent meeting.

The Secretary then read a communication on "Halation, its true cause and remedy," by Mr. Marlow. The object of the writer was to show that the phenomenon, usually known as halation, was the result of the action of light which, having passed through the excited collodion film, was reflected back, and produced the effect referred to. The remedy suggested was the blacking of the back of the plate with black varnish. The paper was illustrated with several specimens to prove the position, the majority of which, however, it appeared, had not been exposed in the camera, but to diffused daylight, the image being formed by partly covering the plate with a piece of black card.

Mr. Shadbolt said there was an old joke to the effect that when the French academy were forming their dictionary, a celebrated naturalist entered one day, and was informed by the assembled *savans* that they had just been defining a crab, and wanted his judgment. They had defined it as "a red fish, which walks backward." "Excellent!" exclaimed the naturalist, "only it is not red, it is not a fish, and it does not walk backward!" The paper they had listened to was an explanation of the cause of a certain fogging by reflection, but certainly did not touch the question of the phenomenon known as halation. That which was known as halation was an increased reduction, which generally took place where very light and very dark parts of an image were in immediate contact, and the greater part of the increased deposit was on the lighter part. It had no distinct outline as these specimens had, but gradually diminished. Even had these results been true cases of halation, there were objections to the theory. For instance, it was well known that light passed through a film of excited iodized collodion with the greatest difficulty.

The Chairman asked how it was, if Mr. Marlow's theory was correct, that halation did not always occur.

Mr. Shadbolt said he did not see how they could with propriety enter into the subject of halation, since it was not really before the meeting, but something else assuming that name. He might remark, however, that halation rarely occurred except when the sun was near the horizon, and the presence of a large amount of organic matter in the bath was a favourable condition.

Dr. Diamond remarked that he remembered on one occasion where the yellow glass of an Archer's camera was accidentally broken, and two coated and excited collodion plates served perfectly well as a temporary substitute, effectually keeping out the light. This confirmed Mr. Shadbolt's view that light would not readily pass through the excited collodion film.

A conversation on the subject then ensued, in which Mr. Malone, Mr. Shadbolt, Dr. Diamond, Mr. Eliot, and others took part, in which it was manifest that much difference of opinion existed as to what halation really was, whilst nothing tending to elucidate the cause or remedy transpired.

Mr. F. G. Eliot then showed a tent and travelling equipment, for working in the field. The chief peculiarity consisted in making the box in which the apparatus was carried form the base of the tent, four upright pieces of wood being placed in grooves in the corners of the box, supporting top cross-pieces over which the canvas was fitted. A large plate-box served as a seat for the operator.

After some conversation on the subject, the proceedings terminated.

Photographic Notes and Queries.

Megascopic Enlarging Camera.

Sir,—Having lately purchased a Megascopic camera (manufactured by Seeley and Garbanatti, New York) for printing enlarged proofs from negatives, will some of your numerous readers, having the same, kindly inform me of a good method of working, as my prints seem to lack sharpness? There are several photographers who have them, and I have seen some good work done with them. They are about one quarter the price of Woodward's solar camera, and, if they can be worked successfully, must be appreciated.—I remain, yours respectfully,

A. B. S.

[Seeley's Megascopic camera is considered, we believe, by Mr. Woodward, as an inefficient imitation of the solar camera; but as we are not aware exactly of the points in which it differs, we can offer no opinion. Our correspondent's request is somewhat indefinite; he neither describes the camera, nor names the points wherein he needs advice.—Ed.]

Substitute for Yellow Glass.

Dear Sir,—I saw in a number of the Photographic News, a few weeks since, a letter respecting the inferior quality of much of the yellow glass used for admitting light into developing rooms. I am now working in a room in which I have a frame five feet by seven feet covered with yellow demy paper, which can be obtained at any stationer's at one penny per sheet. The frame has now been covered more than three years, and I find it quite as good now as the first day on which it was fixed. I can produce pictures in the room covered with the paper above alluded to, either negative or positive, quite brilliant, and without the least signs of fog. The paper should be thick demy. If you think the above will be of any use to your readers, I should be glad if you would be kind enough to give it a place in the next number of the NEWS; and oblige, yours truly, T. S. SWATRIDGE.

Yeovil, March 26, 1861.

COLLODION FORMULÆ.

SIR,—To most amateur photographers, who, like myself. purchase their collodions, it would be a great advantage if the makers, on each sample they sell, stated its exact constituent parts, and also that of the iodizer. I can fancy that somo might object to do so, having, as they imagine, surpassed their brother chemists in their own productions; in such cases we would not desire more than that the collodions be called by their own names; still when we read in your excellent paper of Mr. Blanchard producing *first rate instantaneous pictures* with a bromo-iodized collodion, the formula for which he most kindly gives us, in your last impression, one is anxious to see some respectable house advertising, and guaranteeing to supply such a collodion. The same remarks would apply to the alcoholic one used by Dr. Sanders for his dry plates, without preservative solution, as given in your NEWS ALMANAC. Unless we can obtain such samples of collodion ready made, I suppose there is no other way for it but to prepare our own, for however good may be our productions, we work so much in the dark that we can never be certain of obtaining the samo results when using another sample of collodion even from the same maker. The stereograms of which you made so very favourable and complimentary notice in your paper of the 28th ult. were taken with Mawson's collodion, wet plates, 30 seconds exposure, Ross's lenses, $\frac{1}{4}$ stop. The sensitizing bath I made during the severe frost, and in order to secure pure water melted a quantity of ice, and then passed the liquid through filtering paper. I am persuaded that half the troubles and difficulties amateur photographers complain of and meet with, would be avoided by employing *pure water for making their sensitizing bath.* Ice may be met with all the year round at the stalls of fishmongers, and the cost of it would be far more than compensated for by the satisfactory results obtained.—I am sir, yours, &c. C. F. B.

Langrigg Hall, Cumberland, April 2, 1861.

[Mr. Blanchard manufactures the collodion he described for sale.—ED.]

PORTABLE BACKGROUND.

SIR,—In answer to your correspondent W. H. H., I would say, procure some half-inch deal, about two inches in width, and make four frames three feet square outside measure, hinge two together with two small hinges, which we will say is the bottom half of the background, the other two, hinged together in the same manner, will be the top half, now these two halves to be bolted together with wooden plugs.

Get four yards of green baize cut in two, sew the two pieces together, press the seam, which is now to be what the tailors' call "wranted," I think it is drawing the nap of the baizo over the seam with green cotton, so that it does not show in the picture. This is to be stretched on frame.

The hood at the top for this blue lining will do supported on top of frame by slight deal oblique stays. which have shoulders that fit into corresponding holes in background frame, and into each other.

When taken apart, and the two halves strapped together, this background frame will of course be three feet square, and easily caried under the arm.

	s.	d.
Cost of frame	3	0
,, baize	6	0
,, blue lining	0	9
Total ...	9	9

N. W.

SIR,—Your correspondent W. H. H. may make a background that may be rolled on a roller easily, and unrolled without creasing, thus:—Stretch a piece of calico sheeting,* seven feet long, on a frame, or tack it against a wall, then size it over with thin glue size, when quite dry paint it with soap flatting made as follows:—Have some lamp black, white lead, and venetian red, ground up in as *little oil* as possible, mix this with turpentine till it is a dark mouse colour, then shave one ounce of common yellow soap into six ounces of boiling water, stir it till dissolved, then add it boiling to one and a half pound of the paint, mix it quickly, and when cold paint over the calico, and, if necessary, give it another coat when the first is dry. When dry the background can be rolled or folded without creasing.—Yours truly,

Heathfield Street, Swansea. THOMAS GULLIVER.

[We are glad to see Mr. Gulliver's name again; his suggestions are always practical and ingenious.—ED.]

* It can be bought two yards wide.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 3rd April, 1861.

As sunshine has been so very scarce during the past year or two, photographers would gladly avail themselves of the electric light as a substitute if it were not so dear. It answers their purpose so admirably that it is most devoutly to be hoped that it may become cheaper, it would then be to the photographer what steam has proved to the mariner, who now has no longer to wait for wind or tide. What a luxury it would be to be able to turn on a miniature sun on a cloudy or foggy day, or at night, to meet the exigencies of portrait or proof.

Some of our photographers, however, to whom money is luckily no object, make very frequent use of the electric light, especially with the so-called solar camera. The method now generally adopted in employing this instrument, is not to place a sensitive paper in the camera, but to obtain an amplified negative from the small positive, and print from that in the ordinary manner. By adopting this method we may obtain as many positive proofs as desired, instead of one at a time by the slow exposure in the camera. In the one case, about three quarters of an hour is required, even in fair weather; in the latter an impression is secured in about a minute. Besides, in the camera process, the sun moves during the prolonged exposure, by which the image becomes displaced, and the sharpness of the picture would be destroyed, were not the operator to kep the apparatus in motion to obviate the consequences of the sun's apparent motion. But this mode of proceeding soon becomes intolerable, even to the most patient of adepts. Now the employment of the electric light obviates, in great measure, these inconveniences. In the hands of the eminent optician, M. Duboseq, who recently experimented before our photographic society, perfect success is attained. In his arrangement, he places behind the collecting lens, in an ordinary amplifying apparatus, a voltaic arc formed of a powerful pile consisting of forty or fifty of Bunsen's elements, so as to substitute for the solar image, usually projected upon the mirror, a fixed electric light, always maintained in one position by a regulator, thus leaving the operator at liberty to engage in other manipulations. By the aid of this light an enlarged negative may be obtained in the course of a minute upon iodized paper.

I am gratified in being able to supply you with more ample details of M. Fargier's carbon-printing process, in which you have expressed so much interest. Up to the moment when the plate is impressed by the action of light, his process is identical with Mr. Pouncey's, or, what is the same, with Mr. Poitevin's; but beyond that point no similarity exists. He takes pure white gelatine, as free from alum as possible, and dissolves about two drachms in a pint of water; to this solution he adds a drop or two of ammonia to precipitate any alum that may be present, and then incorporates fifteen grains of the purest carbon intimately with the liquid; the best carbon is that obtained from the combustion of coal-gas. To effect the complete incorporation of the carbon with the solution of gelatine, the mixture should be well worked under the pestle in a glass or porcelain mortar, adding also fifteen grains of bichromate of potassa, previously dissolved in the smallest possible quantity of water. A portion of this mixture is poured on a piece of plate-glass, and dried at a gentle temperature, not exceeding 140° F. This done, the plate is placed under a negative and exposed to light for one or more minutes, according to the intensity of the light. Thus far, you will perceive, M. Fargier's process presents no novelty; but thenceforward it differs very materially from other known processes. In the latter, when the plate is conveyed to the dark-room, it is washed with water, to remove such portions of the gelatine as have not been acted upon by the light, leaving the insoluble portions which form the picture by the carbon they retain. But M. Fargier does not proceed in this fashion; for experience has shown him that this rough mode of washing removes all the half tones, and leaves only the opaque blacks, in consequence of the solution of those portions of the gelatine contiguous to the slightly coloured portions of the image.

To avoid this inconvenience, M. Fargier has overcome the difficulties in a very ingenious manner. Instead of washing the upper surface of the gelatine, that which has received the luminous action in a direct manner, he places it on a suitable support, aud then washes the lower surface of the film, so that only such portions as are really soluble are removed, leaving upon the support the most delicate half tones and the finest details. To accomplish this result, he proceeds as follows:—When the plate is taken from the printing frame into the dark room, he pours all over the gelatine surface a layer of thick non-iodized collodion: when this has become dry, he places the plate in a dish of water, collodion uppermost. The water penetrates beneath the collodion, and softens the gelatine, which soon becomes completely detached from the plate, and floats in the water: the glass is then removed, and the washing cautiously continued. When this is concluded (it must be performed in a dish with a white bottom, and perfectly flat), a sheet of gelatinized paper is dexterously applied to that surface of the gelatine which was originally in contact with the surface of the glass. It adheres with the greatest facility to the paper, and presents, when dried, a perfect picture with all the charms of nature's chiaroscuro. In dexterous hands very beautiful results may be obtained.

Among the mauy useful applications of glass, one recently made by M. Hubert, of Belgium, is worthy of mention. With this substance he constructs casks of various dimensions, from one gallon upwards. These possess many unquestionable advantages over wooden casks; in the first place, they are stronger, being found to resist a greater hydrostatic pressure without breaking. Next, they are admirably adapted for the preservation of fermented and spiritnous liquids, essential oils, chemicals, &c., as there is no chemical action on the glass, no loss by permeation or evaporation. The glass casks are fitted with ground-glass stoppers, and with glass taps. These do not allow of the contents becoming musty, as with wood; and being transparent, the quantity of liquid contained in them can at all times be readily ascertained. For convenience of handling, a wicker open framework is fitted to them. There can be no doubt that, when their merits are recognised, they will come into general use for many purposes.

M. Chevreul has presented to the Academy the eleventh report on his researches into the chemistry of dyeing. It consists of two parts:—1st. New proofs in support of the opinion maintained by M. Chevreul in opposition to many modern chemists, that the phenomena of dyeing are the result, not only of physical adherence, but also of a true chemical affinity. 2nd. Of the influence of heat, light, steam, and of the mordant in the process of dyeing.

M. Chevreul has now summed up the facts relative to the interference of chemical affinity, by announcing the results of four great series of experiments in dyeing made with picric acid, carthamine, sulpho-indigotic acid, and fuchsine-rose, upon silk, wool, and cotton. These three fabrics are very differently influenced by the above four tinctorial matters; sometimes one, and sometimes another, takes either a deep tone of colour or no colour at all. To M. Chevreul it seems impossible not to admit that these differences are evidence of a true chemical affinity. At the beginning of his communication, the learned professor emphatically declared that without the *cumul* (plurality of offices)—he has underlined and strongly accented this word —without his twofold functions of Professor in the Museum of Natural History, and at the Imperial Gobelins Manufactory, it would have been absolutely impossible for him to have brought his classification of colours, and his chemical researches upon dyeing to a conclusion. It was only at the *Jardin des Plantes* that he could command complete collections of colours from the three kingdoms of nature, where the zealous director of the School of Botany presented to his examination no less than 15,000 hues of leaves and flowers of all countries. It was only at the Gobelins that he could have made the requisite experiments in dyeing, and compose, define, and classify the coloured circles and scales; or could have met with so competent a judge with respect to colouring as the present director of that establishment, M. Perrin. These researches of M. Chevreul are of a nature that would hardly repay the outlay of publication, from the great cost of the illustrations, but owing to the liberality of the *Académie des Sciences*, they will not be lost to the world, as they will form the 33rd volume of its *Mémoires*.

The employment of electricity as a motive power depends on its relative economy with steam, or the difference between the cost of zinc and coal; for in the electric battery it is the zinc that is consumed, and is at present the most economical combustible for the purpose. Yet it is 105 times dearer than coal. Then to the cost of the zinc must be added that of the acids, making, for the same equivalent of power, zinc 200 times more costly than that of coal; or rather, the cost of electromotive power so much dearer than that of steam power. But a remarkable feature in the question is, that while ordinary steam-engines render only 0·052 of chemical power, the electromotive machine yields 0·20 to 0·25, which is enormous, and gives it an undoubted superiority over steam. Yet even at this rate, electromotive power is twenty times dearer than that of steam. The question to be solved therefore, is, the economic production of electricity.'

THE SOCIETY OF SCOTLAND.

Dear Sir,—At the last meeting of the Photographic Society of Scotland, and after the reading of Mr. Wall's paper, Mr. George Harvey, R.S.A., although thinking this communication "a step in the right direction," asserted that "his friend, Mr. Kenneth Macleay, who was a photographer as well as an artist, had informed him that in painting a photograph he always found it necessary to make the eyes somewhat larger than they were represented in the photograph, and it was notorious that the hands, which were usually a little nearer the camera than the face, were rendered disproportionately large." T. B. Johnson, Esq., who then occupied the chair, said that Sir David Brewstsr had proposed a remedy for "*such defects*."

In the name of common sense for what defects? Has Mr. George Harvey ever studied anatomy? or those proportions which derived from the most beautiful and perfect examples of ancient art, constitute rules of acknowledged value for drawing the human figure? Du Piles, quoting Fresnoy, *who derived* the measurements from the never yet surpassed or equalled statues of the ancients, tells us that—"*The hand is the length of the face;*" and Sir Joshua Reynolds, quoting Du Piles gives this and other laws as matters, not of dispute, but of recognized fact.

In nature we find faces unusually long or hands unusually short, but in a well proportioned hand and face Fresnoy's measurement has always been fouud by artists who sought truth the common and correct one. Apply this rule to any photograph of a well proportioned hand and face, and you have at once a demonstration of the fact. With due deference to Mr. Kenneth Macleay—I think the eyes are no more disproportionate than the hands, for although large eyes are unquestionably more beautiful than small eyes, small eyes are far more common than large eyes; and such conventional and hugely disproportionate eyes as our old fashioned miniature painters delighted in rendering are about the most uncommon things in nature.

I think it a great pity that some member of the Society of Scotland did not have a copy of your excellent journal for December 14th in his pocket, that he might have allowed Mr. Wall to reply to Mr. Harvey by quoting from that gentleman's third Dialogue Sketch,* in which he says, "you must know that Crackdbell and many *many* other worthy folk, more vain than wise, believe that this photography is after all but an ill-natured, misanthropical power, delighting in slander and distortion;" that "as to the hands, the best lens you can get will insist upon making them so monstrously large, that they are nearly as long as the face itself, the absurdity of which you may at once prove by measuring your own hand against your own face."

If Mr. Harvey, as a member of a photographic society and an artist, were to bring the truths of photography to correct the conventional untruths of the painter, he would deserve warmer thanks than he will ever obtain from endeavouring to mislead scientific men, and lead astray those who believe that because he *ought* to be a well-informed and trustworthy guide therefore, he is such. I would also commend to Mr. Harvey the example of Mr. Wall, who, while striving as an artist to elevate photography, also endeavours as a photographer to benefit his brethren of the brush.—I am, dear sir, yours, &c.,

A Believer in Photography, and a Lover of Art.

* See p. 366 of the last volume.

ART PHOTOGRAPHY.

Sir,—I can bear it no longer. I must ease the safety-valve, or there will be an explosion. I have silently and patiently borne this severe castigation for the last eighteen months, but I can bear it no longer.

I fancy I hear you with your editorial indignation saying "what's the fellow mean, what's he talking about?" Well sir, I will enlighten your mind, as well as ease my own, by telling you that this castigation is upon "*Art Photography*," which I have received from you, and your esteemed contributor, "A. H. Wall," through the pages of the News, ofttimes making me dissatisfied with my own productions; why, I dont know, unless it is that I am afraid I have not the *sixth* sense which a contributor to a contemporary said was so necessary to make a man an artist. Why, sir, not many weeks ago, when under one of these fits of dissatisfaction, I went twenty miles to see the works of a professed artist-photographer, and what was my surprise to find that my own were not a whit inferior to his, in fact, I was almost vain enough to think mine were superior.

Then in the name of all that's photographic, what's all this "fuss" about? To make you awake to your deficiencies? well, sir, I am quite awake to them; and now begins my complaining; you tell us of our faults, and wants, but don't tell us how to *remedy* them. I have been waiting a long time for that information, without getting it, except the meagre bits that I find worked up with the lessons on colouring, which your kind contributor A. H. W. is writing for a contemporary (for which allow me to thank him), but to be told after six years study of the science, that you are no photographer, is enough to make the choler rise; but I am determined to be a photographic-artist, and therefore, now sir, what I want is, your advice as to the books I should study, upon the *elementary principles of Art, as composition, (not patchwork,) chiaroscuro, breadth, pose, &c. &c.*

Now sir, if you or A. H. Wall, will inform me which is the *best* book or books, upon the above subjects, I shall be for ever indebted to you. An answer in the News will greatly oblige.—Yours truly,

One in search of Art-Knowledge.

[Our correspondent is in a right state of mind if he really be awake to his deficiencies. Where a man feels that the executive hand comes short of what the conceptive brain desires, he must and will progress. But our correspondent has surely not read our pages carefully, when he says we do not give the remedy for the faults we point out. We had prided ourselves on being pre-eminently practical, and had devised a series of articles to convey the instruction required by photographic art-students in a definite form for reference, and entrusted it to a gentleman eminently capable of conveying the right instruction. We refer to the series under the head of "Technology of Art," &c. by Mr. Wall. The object of that series of short articles is to convey the instruction to the photographer in a connected and brief form, which might otherwise be sought in some scores of volumes written more expressly for the use of the painter. If our correspondent read these and the other art articles which appear in our pages, together with the admirable hints on the balance of lines, &c., by Mr. Lake Price, which appeared twelve months ago, he will scarcely have to complain of the want of practical instruction in art as it relates to photography.—Ed.]

THE TANNIN PROCESS.

Sir,—On further trial I find that the quantity of acid to be used in the tannin process developer should be as much as 30 grains citric acid, to 10 grains nitrate of silver, when the subject contains sky and dark objects, and the tannin solution is of the strength of 30 grains to the ounce. For the above class of subjects, the best rule appears to be, to use with each grain of silver, one grain of citric acid to every ten grains of tannin in one ounce of solution. For subjects containing less contrast, less acid may be used. With regard to the modification mentioned in your last, I do not think it will be found to be an improvement. Nearly a year ago, I worked a great deal with gum arabic mixed with tannin, before trying tannin alone, and found that the former gave very good results, but prefer the latter for the following reasons: in my hands the gum arabic made the film less adherent, the glass being previously covered with gelatine, it was somewhat apt to cause fogging, and unless well washed out, would cause turbidity in the developer.

The use of citric acid will no doubt correct the chief fault the process is liable to, blurring at the edges of the sky or high lights; but the most effective way of using it seems to be in the developer, and the acid used in this manner can be varied in quantity, in such a way that the best results may be obtained with all kinds of subjects from plates prepared by the same method.—I am, sir, your obedient servant,

C. Russell.

Stubbers, near Romford, 3 *April*, 1861.

INTENSIFYING NEGATIVES.

In order to prevent the collodion film leaving the plate, it must not be put into the silver solution until it has *set* sufficiently, develop with iron and fix, then pour on a solution of mercury, made as under:—

Bichloride of mercury	1 grain
Hydrochlorate of ammonia... ...	1 „
Water...	20 „

As soon as the image assumes a rich cream-colour, wash the plate *thoroughly*, and pour over a weak solution of ammonia (one grain to ten of water) or hypo. These solutions can be used repeatedly, and do not require filtering.

Having used the above constantly during the last six years, I can speak with confidence of its value in strengthening negatives, *and the film* NEVER *leaves the glass*. If still greater intensity is required, the negative (after the ammonia has been washed off) can be treated with pyro and silver, and repeating the mercury and ammonia solutions; but the progress of intensity must be closely watched, otherwise the film will become too thick, and the half tones destroyed.

A. Brothers.

Talk in the Studio.

Photographic Grouping.—A paragraph we quoted from the *Athenæum* last week on this subject stated, that a recently executed group of the officers of the 84th regiment was photographed by Messrs. Agnew and Son; we find that the *Athenæum* has since corrected itself, and states that the photograph was by Mr. A. Brothers, of St. Ann's Square, Manchester. We have also received a communication from Mr. Brothers on the subject, giving some interesting particulars. The group consists of forty-one persons with some statuary; the size of the picture was 48in. by 21in.; about forty-five printings were nesessary to produce this group, and it occupied fifteen days in the month of December. All the merit of the grouping, which the *Athenæum*—unwilling to conceive as the result of artistic skill in the photographer—attributed to felicitous chance arrangement, like that which sometimes happens in the chromatic combinations of the kaleidoscope, is really due to the care and skill of Mr. Brothers. We are glad for the honour of the profession to be able to state this, and to add that we can, from the reduced copy of the group before us, fully endorse the high opinion of the grouping. Few things are more difficult in photography than the judicious grouping of nearly half-a-hundred persons, to the whole of whom a proper degree of prominence must be given as portraits. Where a number of the figures can be used at will, in any position or in any degree of subordination and prominence, for the mere purpose of producing the right balance of lines and chiaroscuro, the difficulty of composition are much simplified; but where forty-one portraits have to be produced, and the arrangement made with at least some degree of attention to rank and position in the sitters, the grouping requires judgment and skill of the higbest order. We have occasionally seen some fine specimens of portraiture bearing the name of Mr. Brothers, although he has not been, that we remembe, a contributor to our Exhibitions: we hope to see more of his work. We append an extract from the *Manchester Guardian*, noticing this group, because it is gratifying to photographers generally to have a proper recognition of the value of their art from "outside" critics: The artistic difficulties attending the representation of a large apartment full of gentlemen have been surmounted with a skill almost marvellous. Here are neither long lines of heads "all in a row," nor, on the other hand, are the gallant 41 broken up into isolated groups of two or three, lacking all social cohesion. So ingeniously and artistically has the picture been composed, that one's first impression is that Sir George Wetherall has just risen from his chair, and is about to communicate something of importance to the officers generally. There is no stiffness, no attitudinising; all, whether sitting or standing, are in natural and easy positions; and in this crowd of portraits it is obvious at a glance that they are a crowd of gentlemen. At the vestibule end of the apartment are two statues—one of them John Bell's Victory, with outstretched arm, about to place her wreath on the brow of somo hero. By a singular fortuity, it happened that the officer immediately beneath the chaplet is one worthy of being so honoured—being Major O'Brien, who endured, with a portion of the regiment, the privations and miseries of Lucknow, during the temporary triumph of the native mutineers. The portraits are wonderfully clear and sharp; and those in the background have the perspective duly regarded.

Art Patronage.—We have pleasure in noticing that his Royal Highness the Prince of Wales bids fair to tread in the footsteps of his august father in becoming a patron of the fine arts. The number of photographic portraits his royal highness has already sat for, illustrate his interest in photography, and we understand that Sir John Watson Gordon is now engaged on an oil-painting, and Mr John Steele the eminent sculptor, of Edinburgh, is also engaged on a portrait bust of the Prince.

Photography and Architecture.—We notice that Mr. Sheddon, writing in an architectural contemporary, urges on the architectural profession tho advantages to be gained by the adoption of photographs in place of the architectural perspective drawings now in use.

Photography and War.—The editor of the *American Journal*, in commenting on the attachment of a photographer to each regiment in the French army, congratulates photographers on the fact that there will be little danger in active duties, for the photogropher *must be beyond the smell of gunpowder, or his chemicals will not work!*

To Correspondents.

N. W.—The presence of excess of organic matter in the nitrate bath has a tendency to cause irregular reduction in development. Its presence in moderate proportions favours density of tbe image.

Wm. Brown.—Tbe price charged for printing card portraits varies in different establishments. About one shilling a dozen is, we believe, a common price. We cannot state wbich is tbe best machine for rolling prints.

Narberth.—We do not quite understand what our correspondent wants described. The best form of lens for portraiture is the compound achromatic lens, and the best form of simple view lens the achromatic meniscus. For copying, architecture, and many other purposes, Dallmeyer's triple lens. Narberth should pay the postage of his letters wben writing to an editor for information.

F. P.—The *Chemical News* is published weekly, it is edited by Mr. Crookes, and published by Griffin and Co. The price is fourpence. There is no specific work on the subject, the information is scattered in various works. Employ a portrait lens for flowers, &c. An expanding camera is quite suitable for general purposes.

Tit Tat To.—It is better to make a new alkaline gold batb each time it is required for use; but if you consult the article on the subject in tbe Photographic News Almanac you will find a formula for one which may be kept and used again. It is best to use new hypo for fixing, and kaolin should not be used in the hypo at all. A bromo-iodized collodion should be used in tbe Fothergill process, and in tbat case it is best kept ready iodized.

J. C. B——d.—We think you might possibly succeed by making your want known in our advertising columns. Should we bear of anything likely to suit you we will bear you in mind.

J. Kirk.—Transparencies for the magic lantern may be produced either by the superposition of tbe negative upon a dry plate, or by means of camera printing. You will find various articles on tbe subject already scattered through the pages of the News, and we shall have more on the subject shortly.

G. Cockburn.—There are many good instruction books published, so that it is invidious to mention any specific one. See our advertising columns.

Hopeful.—It is best to add the bromide to the iodizing solution. If tbe collodion be already iodized, then dissolve the amount of bromide in the smallest quantity of alcohol possible, and add the solution to the collodion. The bromide of cadmium is the most soluble, and that of ammonia next so. You have misread Major Russell's formula: he says two grains of bromide to three of iodide, and means that proportion to each ounce of collodion. Solarization may arise from several causes; the remedy is either the addition of a bromide to the collodion, or the use of citric acid in the developer. Maxwell Lyte's gold toning formula does not remove the size from the paper.

F. E. G.—The strength of gelatine solution for coating the plates, in the tannin process is 2 grains to the ounce of water. See remarks on the subject in another page. Both gallic acid and pyrogallic acid have been used, and answer the purpose to some extent, but not so well as tannin.

H.—In drying the plate with a spirit lamp take care that it gets equally heated, and not too hot, or it will be liable to crack. A little judgment must be exercised here. If the albumen be poured on the plate gently you should not have bubbles. I can only conjecture tbat in plates 3 and 4 you have either failed to clean the plates thoroughly, or bad immersed them before the film was quite dry. Chloride of sodium may be used instead of chloride of ammonium. In allowing the plate to dry spontaneously there is great danger from dust, wbicb is a great enemy to tbe albumen process. The vessels may be cleaned witb a warm solution of soda and water.

R. N.—The formula for toning without gold was given in the record of patents in the Almanac, and in more detail at page 349 of our last volume.

Phos.—In many respects your formula for instantaneous photography should have given you good results, but we will give you the modifications we think desirable. Your present formula for collodion contains more than twice as much iodide as pyroxyline; use just double the quantity of the latter, which will give you five grains to the ounce, reduce the iodide of cadmium by one or two grains in the quantity stated, and use as solvents equal quantities of ether and alcohol. Add a very little acid to your bath, when quite neutral it is difficult to get clean pictures. Use a 20-grain iron developer with 20 minims of glacial acetic acid, and intensify with pyrogallic acid as you state. The pieces of negative you forward have the appearance of under-exposure, and indicate a bad light. As you do not state the kind of lenses you used, except that they are Ross's, nor the size of stop, we cannot form much opinion of the proper time. You do not state anything of the character of the pyroxyline, it should be of a charaoter tending to to give intensity. If you had not stated that the bath was neutral we should have judged from the negative that it was an old bath containing excess of nitric acid. The stereos you forward are good, but we still cannot conceive how you got good negatives with a collodion containing only 2½ grains of pyroxyline to tbe ounce. We shall be glad to hear of your further success.

Troubled.—You should not attempt to print from a negative intensified with mercury without varnishing, spoiled prints will certainly result.

S. L. K.—Other things being equal, small lens of short focus work quicker than large lenses of long focus. The best test for a silver bath is the mode in which it works; but you may test for acidity or alkalinity with litmus paper. If it turn blue litmus paper red, or any tint between blue and red, it is acid. If not try it with litmus paper whicb has been reddened by holding over the fumes of acetic acid. If it then turn the reddened litmus blue it is alkaline. Positives on glass can be intensified after fixing with cyanide; but unless they are very full of half tone to begin witb, they will make hard unsatisfactory negatives.

J. C.—Positives on paper properly fixed in new hypo are as permanent as toned prints, but they are red and foxey in colour.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32 Paternoster-Row, London.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 136.—*April* 12, 1861.

THE NEW METHOD OF INTENSIFYING.

Since our last we have had opportunity of trying a few more experiments with the method of intensifying we then described, using the fumes of mercury and iodine, instead of solutions and their salts. As regards the simplicity, safety, and efficacy of the method we are more than ever convinced, and feel assured that all those who have facilities for trying it will be gratified with the possession of a reserve power which at times may prove exceedingly valuable.

We stated before that where the negative to be intensified was placed over the iodine first, and then over the mercury, the action did not seem satisfactory. On further experiment we notice the curious fact, that there appears to be no action at all of the mercury on the iodine when that order of exposure is pursued. When the collodion picture is subjected for a few minutes to the fumes of mercury, and then to the fumes of iodine a yellow iodide of mercury is rapidly formed. But if the collodion picture be first submitted to the fumes of iodine, and then to the vapour of mercury, no such action is manifest; the mercury does not appear to have produced any effect at all. But what is more singular, a further experiment proves that the mercury really is deposited, although no iodide of mercury is formed, nor any mercurial coating visible, for on placing the plate again over the iodine after leaving the mercury, the yellow iodide is quickly formed.

There are one or two practical points it may be of interest to name. We notice that when a thin negative has been exposed for a time to the vapours of mercury, it acquires some additional intensity, even without further treatment. When it has been submitted after this to the iodine, it rapidly, as we have stated, acquires a coating of yellow iodide of mercury. This coating is in the first instance superficial, completely covering the surface of the negative in regular gradation, and strengthening the half tones in equal ratio with the high lights. It does not at first, however, permeate the film, a longer exposure being necessary to effect that where it is desired. By the time this yellow iodide has thoroughly permeated the film, so as to show equally at the back and front, it occasionally happens that a great and sometimes irregular accumulation of red iodide has taken place on the surface. This will be removed on application of the varnish; but to prevent any chance of stains or patches occurring, we have poured about a drachm of alcohol on to the film, allowing it to flow all over, which has at once dissolved and removed all irregular surface deposit, leaving only an even film of bright yellow.

From some questions we have been asked it may be desirable to state, that no deposit of mercury or iodine takes place except where a previous deposit of silver has existed, consequently the deep shadows remain untouched; but the slightest deposit of silver, indicating the faintest half tone, receives a deposit, and becomes definitely marked where it had appeared latent before, so that an increase of softness, detail, and gradation, rather than any tendency to hardness is the result.

We have used for protecting the film a benzole varnish; but we see no reason why any good varnish should not perfectly answer the purpose.

TURPENTINE WAXED-PAPER PROCESS.—A NEW DRY PROCESS.

We have received from the Rev. J. Lawson Sisson, of Lausanne, half-a-dozen stereo negatives by the turpentine waxed-paper process, with which we are at once delighted and surprised. For sharpness and delicacy, vigour combined with exquisite gradation, together with freedom from granulation, we have seen nothing in waxed paper to equal them. It is not saying too much to describe them as nearly equalling some of the finest collodion negatives, whilst they far surpass many. The only waxed-paper pictures we have seen which, in our estimation, equalled them, were a few we saw some months ago, taken by Mr. Hooper, by printing in the pressure-frame from glass negatives, produced in the course of some experiments with a modified waxed-paper process, but which, if we remember rightly, did not succeed satisfactorily in the camera for negatives. As Mr. Sisson states, he has not any new particulars to communicate regarding his process, we apprehend they are produced by the method described in his pamphlet, published by Marion. Than the delicacy of definition exhibited, obtainable by this process, nothing finer could possibly be desired for large pictures, and for those gentlemen desirous of using Mr. Sutton's panoramic lens and camera, but are deterred by the real or imaginary difficulties of manipulation, these difficulties are reduced, by a process like this, to child's play.

We have also received from Mr. Sisson some very fine stereoscopic prints, amongst which we find two that arrest our attention by the description on the back, which is to this effect, "A new *dry* process (not preservative, but dry) developed with iron: time of exposure ten seconds," in another the time of exposure is "fifteen or sixteen seconds." There are no details as to lens, aperture, or light; but we, nevertheless, arrive inferentially at the relation in rapidity this bears to other dry processes. In the same parcel are other stereographs described as by the raspberry syrup process, in which the exposure in sunlight has been two minutes. We apprehend, therefore, that the same lens and stop were used in both cases. If inference be correct, we have a dry process eight or twelve times as sensitive as the raspberry syrup preservative process, which possesses at least average sensibility amongst dry processes. If we are right this is the most rapid dry process, except that of Dr. Hill Norris, in existence.

We have no particulars of the nature of the process, but we have written to Mr. Sisson asking for such particulars as he may wish to publish; which, if we receive, we hope to lay before our readers at an early period.

SOIREE OF THE PHOTOGRAPHIC SOCIETY.

The soiree held in connection with the Photographic Society on the evening of Thursday, the 4th inst., in the large hall at King's College, was a complete success. We are not aware how many cards of invitation were issued, but the attendance was great, not less, we imagine, than five hundred persons being present. These comprised, in addition to members and exhibitors, a large portion of the *elite* of literary, artistic, and scientific society, amongst whom we may mention specifically a large number of members of the Royal Society. There was also, as might be anticipated on such an occasion, a large attendance of beauty and fashion, adding their charms to those of science and art.

The large hall of the College was adorned by the majority of the photographs from Pall Mall, which, from the ample space afforded for judicious arrangement, and the excellent light, were seen, in many cases, to much greater advantage than in the original exhibition. There was, in addition to these, a large number of photographs which we had not before seen exhibited; amongst which we may name, as having especially come under our attention, some of the exquisite specimens of coloured and uncoloured portraiture by Mr. T. R. Williams. Mr. Rejlander was present with a portfolio of his gems of photographic art, which enchained the attention of many, but which for their full enjoyment require a quiet hour without the distracting circumstances of a fashionable soiree. We may mention one of the pictures in Mr. Rejlander's portfolio, which interested us much; it is a portrait of that gentleman himself in the costume generally worn by Garibaldi, and the likeness of the two heads, judging from the published portraits of the Italian patriot, is quite startling. A frame of photographs executed by Messrs. Spiller and Crookes, showing the various stages of the eclipse of last July, excited much attention. The photography was very perfect, and the series possessed a scientific interest not surpassed by anything in the room. A frame of instantaneous stereographs of Madeira also arrested our attention by their excellence, many of them being similar in subject to those of Wilson, of Aberdeen, to whose productions they were scarcely inferior. The name of the artist escapes us at this moment.

We must not omit to mention as exciting much admiration some most exquisite sculptures by Durham. A child nursing a dog, hushing it to sleep, is one of the most charming things we have seen; folding it tenderly to the bosom with one arm, the finger of the other hand is held up admonitorily, the title being "Go to sleep!" The whole pose, sentiment, and treatment are perfect. The fact that Mr. Durham is a photographer, and a member of the Council of the Society, will not lessen the interest of his sculptures in the eyes of photographers.

Several tables, displaying apparatus and chemicals, were exhibited; amongst the firms thus represented we may mention Messrs. Murray and Heath, Horne and Thornthwaite, the London Stereoscopic Company, and Mr. Solomons. Some of the chemicals exhibited by Messrs. Horne and Thornthwaite deserve mention as very fine specimens, beautifully prepared; a sample of chloride of gold excited much attention from the mode of its crystallization.

The stereotrope, or stereoscopic thaumatrope, invented by Mr. Shaw, was exhibited on one of the tables, and excited much attention. The object of this instrument—exhibiting stereoscopic objects in motion—has been before described in these pages. We could not examine it with minute attention in the room; but whilst, undoubtedly, very ingenious, it struck us that the effect was not very perfect. The objects exhibited were to show machinery in motion, and that motion struck us as jerky and unnatural, and not as suggestive of the calm, resistless power with which we are generally impressed on viewing the motion of machinery.

Refreshments were served in the library of the College. Altogether the arrangements were very perfect and successfully carried out, the result being that enjoyment and satisfaction were universally apparent. We repeat, the soiree was a great success.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analylsis.

An account of the various chlorides which are used in photography will appropriately follow a description of the iodides and bromides. First in importance stands common salt—or *chloride of sodium.* This important body is obtained for commerce either by extraction as rock salt from salt beds, which occur in various parts of the world: or by the evaporation of sea water, either in the sun or by artificial heat. The properties of chloride of sodium are so well known that any detailed description is unnecessary. It crystallizes in cubes, octohedrous, or hollow square pyramids; it is either transparent or translucent. When it has been rapidly crystallized it decrepitates in the fire, owing to its having enclosed some of the mother liquor, mechanically between the individual crystals. It fuses at a red heat, and forms a crystalline matter on cooling, at a white heat it volatilises. One part of salt requires 2·7 parts of water to dissolve it; and there is one curious property which characterises this salt, which is, that it is equally soluble in water whatever be the temperature, boiling water not dissolving more or less than water at the freezing point. It is slightly soluble in dilute, but almost insoluble in absolute alcohol.

The impurities in commercial salt such as is used for culinary purposes, may be iodide and bromide of sodium, sulphate of soda, chlorides of magnesium and calcium, and sulphates of magnesium and calcium. These give it a sharper, and more bitter taste, and may be separated by dissolving the salt in water so as to produce a saturated solution, and then evaporating at a gentle heat to half its bulk. Chloride of sodium will crystallize out, whilst the impurities will remain in solution. In cases where there is a great amount of sulphate of lime present, this will separate with the chloride of sodium, and must be separated by precipitation. For this purpose add to the liquid a weak solution of chloride of barium, drop by drop, until no more precipitate falls down; then filter from the precipitate, which will contain all the sulphuric acid in the form of sulphate of baryta, and add to the clear filtrate a dilute solution of carbonate of soda until all the baryta is precipitated, boil the liquid well and filter. The excess of carbonate of soda present must then be neutralized with hydrochloric acid. The solution upon evaporation will deposit pure crystals of chloride of sodium.

The insolubility of chloride of sodium in alcohol has prevented its being employed in collodion, for this purpose other chlorides must be taken.

Chloride of Ammonium, or sal-ammoniac, is prepared on the large scale either by the distillation of soot prepared on purpose by a particular method, or by neutralising crude carbonate of ammonia with hydrochloric acid or a chloride; or it is first converted into sulphate of ammonia by mixing it with sulphuric acid or a sulphate, when it is easily converted into chloride of ammonium by heating it with common salt. The salt is generally separated from most of its attendant impurities by sublimation, whereby it is obtained in grey or brown-coloured cakes of a fibrous texture. From these it may easily be obtained pure by a second sublimation on the small scale, or, as that operation may be difficult for amateurs, by dissolving as much in water as the latter will take up at a high temperature, filtering whilst hot and cooling. As the temperature becomes lower, chloride of ammonium crystallizes out in white crystals. These, when collected and dried, will be quite pure. Chloride of ammonium crystallizes in regula roctohedra, cubes, or feathery crystals. When in lumps it is difficult to powder. When heated it volatilizes undecomposed and without previous fusion. It is permanent in the air, of a sharp saline taste, and is neutral to test paper. When exposed to the air, a solution of chloride of ammonium loses ammonia, and becomes acid to test paper. For this reason the solution of the salt should not be employed for delicate photographic work, after it has been long exposed to the air. In this case it must be tested with blue litmus paper, and if it shows an acid reaction a little ammonia must be added till neutralised. One part of chloride of ammonium dissolves in 2·7 parts of water at the ordinary temperature, and in its own weight of boiling water. It is sparingly soluble in alcohol, although more so than the corresponding sodium salt.

Chloride of Barium is a very important chemical, both to to the photographer and scientific man. It is prepared in commerce in several ways; one of the simplest is by decomposing an aqueous solution of sulphide of barium (obtained by igniting heavy spar, or native sulphate of baryta, with carbon) with hydrochloric acid. The liquid is then boiled for some time in a porcelain dish, until all the sulphuretted hydrogen is evolved, when it must be filtered from the precipitated sulphur, and evaporated to the crystallizing point; on cooliug, chloride of barium separates. Another plan. which might be advantageously employed in some localities, is to decompose the native carbonate of baryta by means of hydrochloric acid. The two are mixed together, and boiled in a glass or earthern vessel until no more carbonic acid is evolved, when the liquor must be filtered, evaporated, and crystallized. In either case the crude salt must be partially purified by solution in water and re-crystallizing.

The commercial salt may be contaminated with several impurities, such as chloride of strontium, chloride of calcicum, chloride of aluminum, sesquichloride of iron, and sometimes cyanide of barium. The first and second impurities (chlorides of strontium and calcium) may be removed by finely powdering the salt and boiling with moderately dilute alcohol. The two chlorides dissolve out and leave the barium salt free from them. Chloride of aluminium and sesquichloride of iron arise from the presence of clay and oxide of iron in the mineral. They are decomposed by exposing to a red heat, or they may be precipitated by boiling with baryta water, or dissolved out, like the previous chlorides, by means of alcohol. Cyanide of barium is a very rare impurity; it may be detected by its giving a blue colouration with salts of peroxide of iron. If present it may be removed by boiling the salt with hydrochlorie acid.

Pure chloride of barium crystallizes in transparent colourless tables, which are permanent in the air. They decrepitate in the fire like chloride of sodium, and probably from the same cause. They are of a bitter, sharp, and unpleasant taste, excite nausea, and act on the system as a strong poison. 100 parts of water at zero dissolve 32·5 parts of the chloride, and at the boiling point 78 parts. If hydrochloric acid be present much less is dissolved, the strong acid dissolving hardly any, so that a saturated solution in water is precipitated by it. It is almost insoluble in alcohol, 1 part of the salt requiring no less than 4857 parts of boiling alcohol to dissolve it.

Chloride of Strontium.—The simplest way to prepare this salt is to ignite cœlestine (native sulphate of strontia) with one-third of its weight of charcoal, to extract the mass with hot water, and then to saturate the filtrate with hydrochloric acid in the way recommended for the preparation of chloride of barium. It crystallizes in long, six-sided needles, containing six atoms of water; when heated they fuse and are converted into anhydrous chloride of strontium. They deliquesce only in moist air, dissolve in less than their own weight of cold water, and in every proportion of hot water, like the baryta salt it is precipitated from its aqueous solution by hydrochloric acid, although not so completely.

The chief value of chloride of strontium to the photographer resides in its great solubility in alcohol, by which it can be employed for the purpose of chlorising collodion, to which it communicates valuable properties. One part of chloride of strontium in crystals requiring only 24 parts of cold and 19 parts of boiling absolute alcohol for their solution, whilst in dilute alcohol they are far more soluble.

PRINTING ON IVORY.

BY SAMUEL FRY.

THIS department of the art of photography is one that of necessity comes more under the notice of the professional photographer than the amateur, as prints on ivory have, until they have been under the pencil of the miniature painter, no especial feature which renders them of particular value.

The first desideratum, and one in which it is necessary great caution should be used, is the selection of the plates of ivory. There are now in the market two kinds, presenting very different appearances. The first is that which is well known as leaf ivory, and is cut across the grain of the tooth, according to the size of which it displays more or less of what are technically known as mackerel marks, which are much more strongly developed in some plates than others. But care should be taken to choose cuts from the centre of the tooth, where there is a considerable space without these marks, which on printing the picture come out very strongly, and when they happen to strike across the face of a miniature can scarcely be overcome by the painter. The second kind of ivory is that known as twist ivory, and is so called from its being cut by a saw working vertically, whilst the tooth or tusk is pressed hard against it at an acute angle; the result is, that, by the tooth being made to revolve, a sheet of ivory is obtained, far larger than can be cut transversely from even the largest teeth, and possessing also the important advantage of having no grain or mackerel mark in it. But there is another side of the question; this ivory is so much more expensive than the other, that where only small pictures, say not more than 3¼ by 4¼, are to be produced, few would incline to pay the price, and for my own part, where the opportunity of selection is at hand, I should choose those pieces of the ordinary leaf ivory, which have the broadest space in the middle without grain; these plates should have one side smoothed, till all saw marks are obliterated, and the surface is as polished as a piece of writing paper, and all pieces not in this state should be rejected, although by means of fine emery a very near approach may be made to it. Having chosen the plates of ivory, the next step is to bring the prepared surface into a proper condition to receive the impression, and which is thus accomplished. Prepare a mixture thus:—

Albumen	... ...	1 ounce
Chloride of sodium	... ...	3 grains
Citrate of soda	... ...	3 „
Ammonia liquor	... ...	3 min.

Let the mixture be most diligently agitated by a whisk until it is all froth. Now put aside, and allow it to settle down, when it may be decanted for future use, as the ammonia will preserve the mixture from decomposition, and it will improve with age, until three or four months old; to use this solution take a good rigid camel-hair brush, I prefer a flat one, half-an-inch wide, and lay the albumen carefully over the smooth side of the ivory, taking care to pass the brush in the direction of the grain, and straight down only, not up and down; when the surface is quite smooth put it aside to dry on the back, out of the way of dust, and, if possible, in a room of which the temperature is not lower than 70° or 80° Fahrenheit, as the albumen at this heat dries on the surface, and is less troublesome at a subsequent part of the process. These plates should be wrapped up when done, each in a separate piece of tissue paper, to avoid scratches. When a picture is to be printed, float a sheet of ivory on a small quantity of eighty-grain solution of nitrate of silver. It is of great importance to be quick in placing it on, as the plate curls up instantly, and if it have not touched the fluid all over, or if there are bubbles under it, it is very probable that, in attempting to rectify this, that the solution will get on the back of the plate, and thereby cause marks of more intense action in the picture at the parts over the spots.

The sensitizing should always be done in the dark room, as the action of light on the animal substance of the ivory when covered with the surface of the chloride of silver, is far more rapid than on paper, either albumenized or plain salted.

When the floating has continued for three minutes, remove the plate with horn pincers, and set it up on end to drain for a few minutes on a piece of bibulous paper, which done, lay it on its back in a drawer or cupboard to dry, meanwhile preparing the negative for producing its print in the following manner: the great distinction between printing on paper and on ivory is in the fact, that the former, when in the pressure-frame allows the progress of the picture to be inspected by bending in the middle; whilst the latter being rigid cannot be so treated. It is, therefore, necessary to take a piece of white note-paper, the size of the negative plate, gum one end of it a quarter of an inch deep, stick that end at the back of the lower part of the negative, then turn the paper round to the face of the negative.

Now take the plate of ivory and place at each corner of the back a touch of gum, then lay it on the face of the negative in its right place, and turn the piece of paper, already in place, down over it, the gum at the corners of the ivory will adhere to the paper, and it can now be all put in the pressure-frame together. As I just noticed, the printing is very rapid, and should have great attention, and the frame never be opened but in the yellow-room, or all the finest tones are soon lost.

To see the progress of printing it may be taken quite out of the frame, as the paper keeps the ivory in position.

The over-printing should be considerable, as in the subsequent processes it is often the case that much reduction is made in the intensity of the picture.

The picture, as we may now call our production, being removed from the frame, wash it in running water for ten minutes, rubbing it carefully on the surface with the finger, when it will be found that the whole of the albumen will rub off as a powder, *leaving the picture on the very surface of the ivory*, and with the pure face of that beautiful material unsullied. I know very well that at this point the practical photographer will exclaim, "but albumen is rendered insoluble by contact with nitrate of silver, and cannot be removed;" so thought I, but it will be found that there is no difficulty whatever in rubbing it off under a stream of water, and the plate may then be transferred to a fixing bath of gold as usual for paper; but as the picture, when painted, will be of considerable value, it is of vital importance that the bath be strong of gold and hypo, and by no means acid. About ten minutes is sufficient to produce a good colour, and one well suited for painting on. I find that generally preferred is a purple or dark sepia tone, rather than black, which often presents great difficulty to the painter in fair complexions. Now remove the plate to a bath of strong new hypo for ten minutes, and thence to running water, in which it should be rubbed with a sponge for the first ten minutes, directing the stream full on the plate. It should be left to wash in this stream of water for twelve hours, and then taken out and dried with a silk handkerchief.

It is now more than likely that on placing the picture on a piece of card it will be found too dark for painting, in fact, it is as well it should be so, for by the next process the tone can be regulated with such exactness that it is unimportant how dark it now looks.

Prepare a weak solution of cyanide of potash, say 5 grains to the ounce of water, and use it for no other purpose than the one now to be indicated, and above all things avoid using it for dissolving the iodide of silver from negatives, the result being that the solution becomes charged with cyanide of silver, and utterly destroys the ivory picture in a very short time. Now take a camel-hair brush and go carefully and very rapidly over the background of the picture with this mixture, working carefully round the hair, and it will at once be seen the colour is giving way under the cyanide, continue this treatment until the whole or nearly all of the background is gone, and the ivory left as clear and white as before any chemical operation was commenced on it, on this the painter, of course supposing he possesses the requisite talent, can produce those lovely effects for which ivory is unsurpassed by any known material. Now with the same solution go rapidly all over every part of the picture which requires to be made lighter, and by having a brush at the other end of the pencil dipped in water, the action may be moderated to any extent. By this means, in skilful hands, and after a little practice, excellent effects may be obtained,—heavy sombre shadows removed, a frowning forehead made more cheerful, high light judiciously thrown, leaving the clear surface of the ivory covered only with a delicate tint on which the painter can by transparent colours give the finest of flesh tints, and all that play of colour which the artistic eye perceives in the human countenance, with a force, vigour, and correctness to nature, such as can rarely if ever be approached by means of any other medium. When the cyanide has played its part, wash for five minutes under running water, and from its complete and ready solubility the removal is easily effected.

It will be perceived long ere this by my reader, who is *au fait* at photographic processes, and in the habit of drawing inferences therefrom, that the two main principles involved in the process I have described are, first, the supporting the picture on the surface of albumen, which, having fulfilled its object, is removed; and, secondly, the production of any required depth of picture, and the clear background, by means of the cyanide of potassium.

Were the albumen omitted, the solutions would sink into the plate, and the result be most unsatisfactory; and, on the other hand, it is seldom that without the use of the cyanide the exact tone is produced, from the fact of the ivory drying up, several shades darker than it appeared when wet, as a plate of ivory when thoroughly soaked in water is very transparent. I am also inclined to believe that a picture, which has been under the action of cyanide, is more securely fixed than when it has been under hypo only; but it is necessary that most copious washing be given to the picture between the operations, or stains are produced by the mutual action of the two chemicals. It will not be a matter of the smallest surprise to me to learn, on the publication of this process, that some one else has also discovered it; but I have never at any time either read or had described to me any process, either in detail or in part, which had for its object the production of a photograph on ivory; and though repeated requests have been printed in the journals for information, no reply of any kind has to my knowledge been given.

It is far from impossible that those engaged in the production of photographs on ivory as a professional affair may raise objections to parts of my process, but my answer to such would be the good results obtained.

In conclusion, if I have been prolix or tedious in my description, it arises from a wish to give the fullest instruction on every detail of the process; and those in the habit of trying new processes will readily forgive the writer for his errors in this direction.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Breadth.—That quality which groups the lights and shadows into separate masses, so as to avoid the spotty, complicated effect of light and dark, of which a chess-board may be representative. Breadth must be considered, in connection with other pictorial requisites, such as *repetition*, balance, &c., but at the same time its importance stands before them all; its simple grandeur of effect and its vital consequence are such that it must govern every portion of the work The forms must be grouped and the outlines selected with a special view to this, while the lights and lighter tones must be massed together, as also the darks and the shadows; the lights being diffused from their focus, the sombre tones from theirs, and equal contrasts being carefully avoided. Where breadth exists, other pictorial qualities must be; where breadth is not, all other pictorial qualities have but small value. You cannot well overrate its importance. Crude patches of light or dark destroy it. Harmonious gradations at once secure it. Perfection of detail will not banish it, nor does the absence of detail produce it; let those who think the contrary say what they will. The mind and power of the artist stooping to the wearying and exhaustive labour of securing minute detail may become weakened, and thus other qualities of higher importance be sacrificed; but photography produces the most minute and delicate details by far different means, and the artist photographer will find, as Delaroche said, that "the finish of inconceivable minutenesss disturbs in no respect the repose of the masses, nor impairs in any way the effect of the whole." Ruskin, writing of breadth, says, "the character of the whole composition may be broken or various, if we please, but there must certainly be a tendency to consistent assemblage in its divisions. As an army may act on several points at once, but can only act effectually by having somewhere formed and regular masses, and not wholly by skirmishers; so a picture may be various in its tendencies, but must be somewhere united and coherent in its masses. Good composers are always associating their colours in great groups; binding their forms together by encompassing lines, and securing, by various dexterities of expedient, what they themselves call 'breadth;' that is to say, a large gathering of each kind of thing into one place; light being gathered to light, darkness to darkness, colour to colour. *If, however, this be done by introducing false lights or false colours, it is absurd and monstrous;* the skill of the painter consists in obtaining breadth by rational arrangement of his objects, not by forced and wanton treatment of them * * * *Generally speaking, however, breadth will result in sufficient degree from fidelity of study—nature is always broad;* and if you paint her colours in true relations you will paint them in majestic masses." *Indiscriminate* imitation, however, must not be relied upon; the few photographs that exhibit real breadth go to prove this. The educated eye may find but little difficulty in selecting such views as produce breadth; but the quality won't seek, it must be sought. Breadth of chiaroscuro will, for landscapes, be most readily found when the shadows begin to lengthen and the light comes from either the right or the left, but much will, of course, depend upon the character of the view. The photographer, whose aims are bounded by the mechanical, will exclaim, "What control have I over these matters? I must take things as they are." True, and so must the painter—but here lies the difference. You clap down your camera, focus your view, calculate the exposure, and so go your way; while the thoughtful artist, whether painter or photographer, gazes long and steadily upon the scene—moves here to avoid taking that into his picture, or there to get in this—moves forward to enlarge one object, or backward to diminish another—shifts his position to escape getting the illuminated portion of a group of trees which it is desirable should be all half tones and shadows, or again shifts to escape a patch of dark shadow which comes crude and harsh against his mass of lights, &c. &c. &c. Contrast your production with his afterwards, and you will understand the value of all this additional head labour. The one has, even to the commonest observer, a mysterious charm attracting and retaining every gaze, the other is little, commonplace, and uninteresting. The one intellectual, the other mechanical. The one is noticed merely from its method of production, the other is a work of art winning admiration from its own intrinsic beauty, without hardly a suggestion of the means by which it sprang into existence. Another feature in this quality of breadth is the feeling of unity and repose which it engenders—there is nothing violent, jerky, harsh, or crude—harmony pervades every part, and unity makes the whole perfect. If you want to secure breadth, avoid "*patches,*" let every demi-tint and every dark belong to a group of a similar kind, and the two groups be themselves associated as a whole. There are those who, misunderstanding the term breadth, imagine that it merely signifies two or three patches in the place of many; who, hearing that a chessboard represents the reverse of breadth, suppose that to sweep all the darks into one corner, and all the lights into another, would produce this much-sought quality in all its charms. But this would only decrease the number of patches without at all changing their character. The great Titian wisely described breadth by pointing out a bunch of grapes, in which, although each individual grape had its due rotundity and character secured by light, shadow, and reflection, the illuminated side formed one broad mass of light, and the shadowed side one broad mass of dark—the one being, nevertheless, sweetly united with the other as parts of the whole. Sir Joshua Reynolds said, "the slightest sketch where this breadth is preserved will have a better effect, will have more the appearance of coming from a master-hand, that is, in other words, will have more the characteristic and *generale* of nature, than the most laborious finishing where this breadth is lost and neglected." Nothing is more destructive of this much-lauded quality than the patch of white photographers have so frequently placed where a sky should be. Howard, in his "Sketcher's Manual," says, "The definition of the quality termed 'Breadth' involves an apparent paradox. Breadth of light or shadow does not mean a broad space of *equal* light or *equal* shadow, that is, Flatness. Breadth is used in contra-distinction to Spottiness; and a space of equal light, *however broad,* is but a spot or blot. There is an abruptness or harshness, in Flat or equal light and equal shadow, that is totally destructive of pictorial effect. A few remarks on the choice of light may assist the photographic amateur in securing breadth. When the light is limited to some one source—such as a window or similar aperture—the depth of the shadows will be in proportion to the strength of the light. Should the light be very bright, the shadows will be very dark; and it will then be necessary so to arrange your model or models that the rays do not by striking some prominent portion of a part, surrounded by intense shadows, create a crude patch of light, where all should be kept subdued and low in tone, as this would destroy breadth. In dull weather out of doors, the shadows are so faint as to be scarcely visible, and there is then consequently very little chance of obtaining breadth. In direct sunlight the shadows are clear and well defined, but by no means strong, owing to the presence of very powerful reflected light. The altitude of the sun rules the length of the shadows, which are longer in winter than in summer, because the rays (which are always *in effect* at least parallel), then fall more obliquely. If the light fall full on the view from behind your camera, there will be some difficulty in obtaining breadth, and so there will be if the light be immediately before the camera. When the sun is concealed by clouds, the lights and shadows grow indistinct, but frequently while this is true of one part of the landscape, some opening in the clouds may give to another part quite a contrary effect. Taking advantage of such *accidents,* excellent effects of breadth are obtained. Cast shadows too, being always darker than mere shade, may be frequently sought to aid in securing this quality. When you wish to obtain a little of more powerful lights and darks in your picture, for the sake of breadth, you may remember that the nearer objects are to your eye, the more brilliant and forcible are the lights and shadows. All these brief and confessedly imperfect hints are as much to be applied in making a selection from nature, as in composing or designing from the memory or imagination. In nature, lights and shadows vary rapidly in position, intensity, and contrast, and the artist can generally discover such a point of view, as will tend to produce ample breadth of chiaroscuro, if he have but the patience to wait, the diligence to seek, and the eye to detect. In concluding this subject I will add one more quotation from George Barnard's work on landscape painting. "*Art can never surpass nature,—the grandest effects produced in pictures are but feeble in comparison to the glorious reality. Let us examine then with the greatest care, those circumstances and effects best adapted to charm the eye, once understood, they will become firm data on which to found our system of art.*" * * * To constitute a picture there must be a fortunate combination or careful arrangement of lines and forms, and a favourable moment must be chosen for catching the light and shade most appropriate to the subject. The importance of the latter must be at once evident from the consideration that the same subject may present itself under various effects of lights and shadows, many of which would, if represented in a picture, distract the attention from parts more worthy the spectator's notice; *and that it is only by devoting themselves to a careful study of well digested rules, and a constant reference to faithful* *delineations of nature, that students can hope to build up a system which will enable them to express the various sentiments they may wish to convey.*" Thus speaks the painter to artists with brushes and pencils; what is there in such remarks that need be left unsaid to artists with cameras and chemicals?

Photographic Tourist.

PHOTOGRAPHIC RAMBLES IN WALES.—No. 2.

BY J. H. JONES.

Old associations, and the pleasure derived from excursions in the Principality in earlier days, were not without their influence in causing me to make the following excursions with the camera, by means of which I should be enabled to obtain pictures of such places and scenes, which ties of early friendship, warm greeting, hospitality, and pleasant companionship, in my rambles through this beautiful country had endeared to my heart, combining, as the country does, so many features to interest the imagination and to allure the eye.

As I wander through this old birth-place of legends and fairy lore, famed alike for triumphs of the sword, and prizes of the lyre, to how many recollections does it give rise, as I look back to those bright days so indelibly impressed on memory's tablets. Like the wearied pilgrim from some far off clime, I seem to renew my existence as the scenes familiar to my boyhood dawned upon me; again I breathe the freshness of the morning hour; while my mind is filled with pleasure, for I was once more amidst the wild blue hills of Cambria.

How often has a strange feeling of the fleeting tenure of all human enjoyments filled my heart, as I have bent my steps to some ancient castle or ruined abbey, which has been the retreat of those who have long since passed away.

Many an hour and many a day have I spent in my boyhood, exploring the wildest recesses of the old glens, and lakes, and hills. And where is the human being who has not, like myself, had reason to contemplate with sensations too strong for utterance, some well-remembered spot—who has not felt himself belonging to the past, even while by his anticipations he has turned tremblingly to catch the shadows of the mysterious future?

It is in the presence of the monuments of ages passed away—of a beloved country whose fame and splendour have vanished—that we can best sympathize with the transient show, and the sufferings of humanity, like the vanquished Roman of old, who sat down amidst the ruins of a fallen empire and wept.

In its monumental grandeur—with the foot of heroic nations everywhere upon its soil—no country presents objects of more peculiar and varied interest than Wales.

The prize of contending invaders, it was long the stronghold of genuine British valour, and maintained for upwards of twelve centuries unequal conflicts with nations far more powerful, yielding only on condition of being governed by a prince born in the country; hence, Edward the First's policy in bringing his queen to Canarvon Castle, A.D., 1284, that his son might be born there; from which time down to the present have not the sons of our English sovereigns assumed the name of Prince of Wales, as the proudest of their titles?

Nothing more clearly proves the importance attached to its possession than this simple historical fact. Nor does the voluminous character of the works devoted to its illustration tend to diminish the curiosity with which we retrace its annals, call to mind its former power, and now its great natural advantages, its increasing usefulness and prosperity. No traveller enters the principality without being surprised with evidences of its singular history, its numerous antiquities being no less striking than its splendid and romantic scenery.

The arena of successive and fierce struggles—commencing with the dawn of the Christian era—here met the Roman, the Saxon, the Dane, the Norman, and all these blending in the resistless English, Cambria still continued to bear a conspicuous part in the grand drama of British power and greatness.

The reduction of the native inhabitants and princes, in their mountain fastnesses, required the lapse of ages, and the strength of combined nations to accomplish. These persevering efforts to vindicate their freedom, gave rise to extraordinary exploits, which, terrible as is the picture of Cambrian wars, powerfully appeal to the imagination and sympathies of the reader. No subject, indeed, could be mentioned which better repays the enquiries of the learned or the curious than the earlier portions of Welsh history.

The scenery of Wales is worthy of its heartstirring associations, it comprises the beautiful and sublime to as great a degree as an equal extent of territory in any country in Europe. Lofty mountains bleak and bare; deep and verdurous valleys; babbling and meandering brooks, shaded by venerable trees beaded with moss, and "standing like Druids old with voices sad and prophetic," or like the native bards with beards that rest on their bosoms.

The scenes I am about to depict will, I hope, prove interesting to all, and be the means of causing some of my photographic brethren to visit them; and if they derive as much pleasure as I do in my rambles through the country, I shall feel amply compensated for these few hints for their guidance whilst in search of the picturesque among the romantic and delightful scenery of Wales.

Some few months ago I had the pleasure of writing a description of the Vale of Neath,* perhaps, therefore, it will not be amiss if I take the sister valley as the starting point on this occasion.

Swansea, or, as it is in Welsh, Abertawe, the most important port in the Principality, is happily situated between two hills, on the western side of the river Tawe, and has been much improved and greatly extended during the last twenty years. The first object of interest is the castle, which I am sorry to say is not so nicely situated as to be "*come-at-able*" for the gentleman of the tripod; but the following places may be selected from as giving very good views of it. The clock tower may be taken from Castle Street, or Castle Square, but the principal view, and, indeed, the most comprehensive, is to be had from the Strand; it is from here that the very elegant open parapet of arches is seen to advantage, and, although the houses in the foreground intrude themselves, still they do not look amiss, as they possess that old tumble-down appearance which harmonizes so well with the castle itself. Several excellent views of the town may also be had from the top of the tower. This castle was built by Henry Beaumont, Earl of Warwick, who, in the year 1099, came into Gower against the sons of Caradoc-ap-Iestyn, and won from them large portions of their territories; he also built several other castles, which I shall mention perhaps in some other future article. By these precautions he fortified himself in this country; and, for his further security, introduced Saxons, as the Welsh historians, ancient and modern, so inveterately denominate the English, to whom he gave lands. Of all the oppressions exercised by the Normans those of Henry Beaumont in Gower were the most intolerable.

In the year 1113, Griffith-ap-Rees, Prince of South Wales, laid siege to the castle and burned everything about it—but he could not make himself master of the fortress: from this time to the year 1648, the time that Cromwell marched here, it was the scene of many contentions, and passed through various hands. In the reign of Edward the Fourth, the heiress of William Herbert, Earl of Huntingdon, the then possessor, married Sir Charles Somerset, an ancestor of the Beaufort family, in which it is still vested.

St. Mary's church is a structure more worthy the visit of the antiquarian than the photographer, as it is built in the

* See Photographic News, No. 84, &c., Vols. iii. and iv.

worst taste of the last century; but it has several relics of the old church, which "fell down" in 1739.

The Holy Trinity church, a recent structure, in the nondescript style of architecture, makes a very pleasing picture; several very nice pictures may also be had of the interior.

The other public buildings of the town, which give pictures more or less pleasing, are as follows:—the Wesleyan chapel, the finest in Wales, should be taken from College Street. The Roman Catholic chapel, in the Gothic style, dedicated to St. David, from Rutland Street; and the Unitarian chapel, in the Tudor style, from the High Street. The "Guildhall," which stands near the docks, makes a charming picture; it was erected in 1827, and was considerably enlarged and improved in 1847. It is now the finest building in the Principality. The south-west and east fronts are rich elevations in the Corinthian order of the Palladian school.

The Royal Institution is the next object of interest, the principal front, which is of Bath stone, extends 100 feet from east to west, in the centre of which is a prostyle portico of four fluted Ionic columns, which order is continued throughout the building; it contains a large collection of antiquities, &c., which are well worth a visit; the library contains the largest collection of books relating to Wales extant. The next and last object worth photographing in the town is the new post-office, which is a very large and handsome structure. A short walk over the bridge which crosses the river Tawe, will bring you to the Danygraig Cemetery, where several very pleasing pictures may be made of the church, the chapel, and the lodge on the grounds; also a very good view of the Port Tenant Copper Works, with the entrance to the harbour and the canal. Just behind the cemetery, but at the top of Killvey Hill, there is the ruin of an old windmill, which, together with a thatched cottage near it, forms a very pleasing picture, especially if the view be taken from the north-east side, the town is seen through two apertures at the base of the hill. Again, another walk to the top of Clifton Hill, on the western side of the river, will give two admirable views of the town, also a good picture of the Grammar School, and in looking to the north-east a beautiful view of the valley, stretching far away in the distance, with the numerous works scattered here and there, give it an appearance of life and activity which adds considerably to the interest of the scene. But I must not stand gazing at this scene of beauty, when we ought to have been on our way to this El Dorado, so if my reader will now accompany me, I will lead him where nature has decked herself in the most charning robes; where rocks, woods, and glens, are gathered together, and vie with each other in attracting the admiring gaze of the delighted and enchanted tourist.

(*To be continued.*)

GLASS-HOUSES.

The following extract from a letter which has come under our notice contains so many practical hints of value on the subject of lighting, that we reprint it for the information of many of our readers, to whom we know, from their repeated enquiries on the subject, it will be interesting. The letter is from one of our first photographers in London, to an operator in the country, who was asking advice on the subject:—

Had you been in the glass-rooms of the best operators here you would have been rather struck with the diversity of their ideas. As a rule, in building a room in London, a person has little choice, but must do it the best he can, according to the accident of its situation, and the space under his control. The mode of lighting materially depends on surrounding or adjoining houses, as the local building surveyors compel us to raise our neighbours side-walls. London glass rooms therefore are mainly top light, not from choice but necessity.

The very best operator, T. R. Williams, has, what would be called by some, a very poorly lighted room, absolutely all top light, and can get no other, but he produces the best lighted pictures we see. My own room is very inferior, all top light, and not lofty enough, hence I have great trouble to get soft pictures, and to avoid violent contrasts of light and shadow. Mayall has been altering his room lately, and has made a great improvement by raising the roof, and a marked improvement has taken place since in his pictures.

Above all things, I say, have a lofty room, ten or twelve feet high, where the sitter stands, and then you may use almost direct light overhead, and yet you have it soft. Decidedly have your glass to the floor if you can, and let the sitter look at the north or north-east, your camera will then be in the south, and have a good-sized box, or screen, to keep the direct light from the lens. My opinion is, that if the sitter is in direct sunlight, or rather in the direction of direct light (say south, south-east, or west) no matter how your blinds are arranged, you cannot depend on soft pictures, and you are at the mercy of every passing cloud. In the other position, by a very little management, you can work without being annoyed with sunshine, at every period of the year and all day long.

It is a very general custom for London people to put sitters on a raised platform, but this arises from the great defect of a small top light, and the sitters have to be raised up to it to get illumination on the lower part of the figure. This raised platform I vote a great nuisance. Silvy has, I think, the best glass-room in London. It is so large that he can put the sitter anywhere, and he thus obtains such striking variety in his "carte" backgrounds, for he has lots of elegant furniture and drapery, and wherever he places them he at once gets a picture. I speak from description, I have not seen his room. H. J. C.

ON THE FADING OF PHOTOGRAPHIC PRINTS.

BY H. H. SNELLING.*

[Whilst the subject of permanent printing excites so much attention on this side of the Atlantic, it may be interesting to record the opinion which prevails amongst our photographic brethren in the United States. Mr. Snelling is one of the earliest American writers on photographic subjects, and was for many years editor of the *American Photographic and Fine Art Journal*, his remarks are made therefore with a full knowledge of the state of printing amongst American photographers. It will be gleaned from the paper that the alkaline gold toning process is not recognised as having yet had a fair trial in the States.]

In deciding any point of fact in photography, practice should take precedence of theory. I shall therefore, in this paper, confine myself entirely to the former, and from it endeavour to show wherein we fail to make permanent photographic prints.

I have no hesitation in asserting that so far as this part of photographic manipulation is concerned, we have retrograded instead of advanced, which I shall endeavour to show by presenting to the society some practical results of ten years' standing.

Particular formulas for toning and fixing are not the only causes of failure. These causes, although very many, can all be avoided. One of the most prominent of these is bad paper; because, under existing circumstances, the most difficult to guard against. Impure chemicals are another source; fixing and toning in the same room used for keeping other chemicals beside those employed for the purpose, is a grievous cause of failure, inexplicable to those who have thus suffered without investigating the subject; toning in the light by some methods; washing in impure water; inaccuracy in making the bath; insufficiency of silver in the paper, and want of care and labour in spreading it on; soaking the paper too long in the salting solution, toning bath and washing trough; and again too long and too short a time given for the final washing, are all causes of failure; these last depending more or less on the quality of the paper. I could mention two other causes, temperature and gas from the stove or grate; and yet two more, in practical use, mounting and finishing.

First, we will consider the paper. Without referring to any

* Read before the American Photographical Society, Feb. 11, 1861.

particular make, I will state the nature of papers from which we expect permanent results. Papers of coarse, loose fibre, sized with ordinary starch sized, such as when held up to the light exhibit a mottled or streaky appearance; or when passed through the salting solution, tear easily and will not bear their weight when hung up to dry, being in fact rotten; or such as are sized in the pulp. Some papers have a slight tinge of ultramarine, which is by no means beneficial—although I am not prepared to say that it is a cause of fading, I think I have detected greater tendency to spot. I have at times detected acidity in papers, the impressions on which began to fade a very few hours after drying. Papers that will not submit to a hearty rubbing, when the nitrate of silver solution is applied with the cotton brush, are unfit for photographic purposes; also those that absorb it so rapidly that it cannot be spread evenly and easily before it gets too dry. Papers silvered and allowed to turn brown and held up to the light showing greater and more dense coloration in spots are of this last character. Good paper is of a fine close-set, mixed fibre, free from cloudiness, streaks, and acidity, hard sized in the sheet with fresh size. It must not tear easily, or become spongy on soaking, and it should stand any amount of rubbing with the buckles' brush. The sizing of papers, good in other respects, may be improved by passing them through a solution of gelatine and rice water, one part of the former to two of the latter. The gelatine solution should be one grain to the ounce of water. The rice water to be made by simmering about four ounces of rice in a pint of water until it swells and cracks, after which pour off and filter the liquor and add it to the gelatine solution.

The faults of impure chemicals are, I believe, thoroughly understood by every one who practises photography, and are easily guarded against by buying of honest manufacturers only.

The toning bath should be kept in a room by itself, where it can be liable to no accidental disturbance. A few drops of sensitized collodion falling into it will start decomposition in the print while in the bath, which will ultimately destroy it; so also will solution or crystals of protosulphate of iron; and it is utterly impossible to fix a print in a bath in the same room with a bottle of sulphuret of potassium, or within reach of cyanide of potassium. I regret that I cannot illustrate all these effects by practical results, as I have not made it a point to keep samples, but I present the society with a copy of *Autumn* [marked No. 1], which is slightly under the influence of this last. In this instance the varnish seems, in a measure, to have checked the progress of decomposition, as the spots have spread very little since the picture was mounted. When sulphuret of potassium acts upon the bath, it produces a muddy yellowish appearance in the print, which decomposes it very rapidly. The iron produces a muddy brown picture. Collodion produces, after a time, yellow spots, which gradually spread to the total destruction of the print.

The decomposition produced by toning in the light is applicable only to those processes where fixing is done after toning.

In silvering the paper, to secure permanency, do not fear labour; the more rubbing it will bear, the more solid and tenacious will be the proof: and, as I said before, if the paper will not bear the necessary amount of rubbing without "fuzzing up," it is unfit for the purpose. Put on sufficient solution to cover the sheet thoroughly, and then rub it in with a buckles' brush, first by circular motion from the centre outwards, and after every part of the surface is well moistened, go over it lengthwise and crosswise, until there is not the smallest chance for the solution to run or drip, after hanging up. I present two pictures, [Nos. 2 and 3], on arrow-root paper, treated precisely alike, except in silvering—No. 3 having been rubbed until it was nearly dry; No. 2 suspended dripping. I think it is not difficult to judge of the quality or permanency of each print. I may say here that arrow-root paper gives fine, solid, clear and brilliant pictures, if printed while freshly sensitized; but if kept even four, three or two hours—according to the temperature—after drying, the results are decidedly bad: the print being dingy, weak, and confused, as in the print marked No. 4.

Soaking paper too long in the solutions, or leaving it too long in the washing-trough after printing, has the tendency to loosen its fibre and dissolve the sizing, consequently destroying the cohesion between it and the silver. If the water is impure, the impurities act more readily on the print in this state, and fading is the result. Water should be always filtered, and the print may be left in the washing-trough from six to sixteen hours, according to the hardness of size and firmness of the paper; sixteen hours should never be exceeded, and six is little enough unless sponging is resorted to. I have also found warm water, or extremely cold water, to cause fading. It should be kept as near 70° as possible. On one occasion I had twenty large proofs frozen up in my washing trough, which, when taken out after the usual time, were entirely destroyed; they had changed from beautiful dark purple prints, to yellowish, dirty-looking, abortions—flat, and the middle tints entirely gone. Many photographers advise warm water, but I have found that it invariably weakens the print, and ultimately destroys it.

The results of over-toning are too well known to require comment. It is not, however, always a cause of fading. Sufficient of the sulphuret of silver produced may be got rid of in washing to prevent the advance of decomposition, as illustrated by print No. 5. Out of a large number of these over-toned portraits, none have changed since drying, while others not carried so far have faded. This print was made over three years ago.

The influence of temperature on toning and fixing as a cause of permanency or fading is very great. The nearer the bath is kept to 70°, the better; the effects of excessive heat or cold ultimately being the same, although the print tones much more rapidly in a bath of high than low temperature. If the bath is either too cold or too warm, no amount of after-washing will prevent decomposition. It is also a very bad plan to suffer the prints to lie still in the bath, particularly when it is above 70°. If left thus to tone themselves, decomposition commences in the bath. The more they are turned over and over the better.

Coal-gas escaping into the toning room will induce sulphurisation in the print; the gas, being attracted by the moist paper and attacking the silver, leads to its ultimate decomposition. I once hung up some prints to dry over a coal stove, at the same time others from the bath were suspended in another room; the former dried yellow, and were decidedly *non est* at the end of a month, while the latter remain permanent to this day.

Mounting and varnishing, as causes of fading, may be mentioned; but so much has been written on the subject, that I will merely say a few words by way of caution. It is folly to varnish a badly-finished print in hopes to save it; the varnish itself will often destroy a picture otherwise perfect. In mounting, be careful that the cardboard is not sour, much of it is so. Gum-arabic and dextrine are unquestionably the best adhesive substances; but whatever the article employed, it must be freshly mixed, and care taken that not the slightest trace of acidity be present.

There is another cause of destruction to the photographic prints, at all events to those that are retouched, namely, tobacco. I am not prepared to say that tobacco smoke will produce fading, but I know that its juice will. Having frequently noticed a peculiar decomposition in prints retouched with India-ink and water colours, I was, for some time, unable to account for it. It at last struck me that tobacco might be the cause. We all know how prone the artist is to moisten his brush with his saliva while at work. Here I looked for the cause, and with pipe in mouth I sat down before a fine print to try, the experiment, and as I went over it with my brush alternately moistened the brush between my lips and in a cup of water, being careful to wash out all the saliva before applying it to the water. The result was, that wherever the saliva, impregnated with the tobacco smoke was placed, there decomposition set in, and gradually spread, while the other portions remained unchanged.

(To be continued.)

Proceedings of Societies.

Newcastle-upon Tyne and North of England Photographic Society.

The monthly meeting of this society was held in the Tower, New Bridge Street, on Friday evening, the 5th instant. G. C. Warren, Esq., in the chair.

The Chairman said, that since their last meeting the council, through their secretary, had communicated with Mr. Moule, the patentee of the photogen, for the purpose of having one sent down to exhibit to them at this meeting. A letter from Mr. Moule had been received, intimating his readiness to comply with the council's wish, and also stating that one would be despatched in a few days. Through some oversight in the hurry of business this must have been overlooked by Mr. Moule; but that he had no doubt that, on another communication being sent, it would be forthcoming at the next meeting. He also announced the election of Roger Fenton, Esq., and Lake Price, Esq., as members of the society.

Mr. McKie then drew attention to the tannin process, with which were presently engaged many of our ablest photographers. He gave it as described by some of its warmest advocates. Though unsuccessful in the most of his own experiments, he attributed the cause of failure to the unsuitableness of the collodion he had used. He had been supplied with some by his friend Mr. Laws. With it he had had much better results.

The Chairman.—What kind of collodion did you use, and what was the character of the film?

Mr. McKie.—The first was an ethereal collodion, the film was hard and tough, and split up in the centre during development; the other was alcoholic, which remained on the glass, but had a tendency to break away at the edges.

Mr. Dewar said, that he had prepared several plates with the tannin preservative, but that in no instance had he been able to finish one, some film cracked during development, and others the film left the plate in drying.

The Chairman.—The splitting of the film during drying would be owing chiefly to the nature of the gun-cotton.

Mr. Laws exhibited two negatives he had taken by the tannin process. They were the only two he had prepared. With both he had been successful. The edges of the plates were varnished with varnish. The negatives were handed round, and considered very satisfactory. Mr. Laws remarked that, although he had been so far successful, he, as a professional was still inclined to the wet process for certainty of result.

Mr. North also advocated the wet process in preference to any dry method.

Mr. McKie thought that, although the wet process might be considered preferable by professionals, he, as an amateur, considered that any good dry process would be a boon to such as himself.

The Chairman coincided in this remark.

Mr. Porteus spoke highly of alcoholic collodion for the tannin process. He had experimented with four different kinds, one by a local manufacturer, another by a manufacturer in the south, and two by Mr. Sutton. Mr. Sutton's alcoholic collodion alone gave good results.

The Chairman stated he had seen several specimens of the collodio-albumen process by a gentleman at Darlington, whose confidence in that process was such that he could guarantee the certainty of his plates; he, the Chairman, considered that the slower the process the greater the certainty. If suitable collodion were used and the tannin process sure, it would matter little whether it took an exposure of 1 or 3 minutes, as far as time was concerned. The general fault in landscape pictures was the want of full exposure. Mr. Laws then exhibited a tent of his own manufacture. The whole of the tent was enclosed in a box about 2½ feet by 1 foot 6 inches, and 4 inches deep. The bottom of the box formed a water-tight tray, which was fixed to a tripod stand, upright bars of deal were raised at each corner, which supported the lid of the box forming the top of the tent. Over the whole was thrown the tent cloth, which contained pockets for bottles, &c., light was admitted through yellow cloth. The waste water was carried off by a tube screwed to the bottom of the tray. In working in this tent the operator stood upright; the advantages of this tent were its simplicity, lightness and portability; the tent was well examined, and much admired by the members.

Mr. Hill, of North Shields, introduced to the notice of the members a stereoscopic camera combining several improvements which he had introduced. The camera displayed considerable mechanical ingenuity.

A large number of very fine stereoscopic pictures by several well known artists, were exhibited by Mr. Bunn. Many large pictures were also shown by the members.

Messrs. Wood, Burney, and Brockett were then elected members of the society.

The Chairman announced that Mr. Laws had kindly consented to read a paper at the next meeting "On the Printing of Transparencies."

A vote of thanks was unanimously given to Mr. McKie for his paper, and to Messrs Laws, Hill, and Bunn, for the exhibitions of the tent, camera and pictures, also and to the chairman. The meeting then adjourned to Friday the 3rd of May.

Photographic Society of Scotland.

The sixth meeting of the fifth session of this society was held on Tuesday night in George Street Hall.

The chair was occupied by Sir David Brewster, President of the society.

There was a numerous attendance of members, and the walls of the Hall were decorated with the pictures of Messrs. Claudet, Maxwell Lyte, and Robinson, removed from the Society's Exhibition just closed. A part of the proceedings of the evening being the presentation to these gentlemen of the medals awarded them. Mr. Lyte and Mr. Robinson were unable to attend the meeting; but Mr. Claudet paid a visit to Edinburgh for the purpose, and was cordially received by the society. In presenting him with his medal, Sir David Brewster brought under the notice of the society the numerous inventions and discoveries in photography, for which they were indebted to Mr. Claudet. Talent of research was seldom, he said, combined with mechanical skill in manipulation; but both these were possessed by Mr. Claudet, to whom had been awarded the society's medal for the best portrait in the late Exhibition. He would briefly lay before them some of Mr. Claudet's inventions and discoveries. Among these were the increasing the sensitiveness of the original daguerreotype plate by the use of chloride of iodine, so that the time requisite for taking a portrait in the camera was reduced from ten minutes to a few seconds. This discovery he made in 1841. He had also perfected the image in the camera by his investigations in the achromatism of lenses. And in order to test the exact difference between the visual and chemical foci, he had invented the focimeter. He also had invented another instrument for measuring the intensity of object-glasses; and, in 1843, he had communicated to the Royal Society a valuable paper on the stereoscope. In 1857, he had communicated a paper on the phenomenon of relief in the image formed on the ground-glass of the camera, and founded on this an instrument which he called the stereomonoscope.

The Chairman then alluded to many important communications on matters relating to photography, which Mr. Claudet had made to various societies, and concluded by expressing the pleasure which he had in presenting him, on behalf of the society, with their silver medal, for the best portrait in their recent Exhibition.

Mr. Claudet having acknowledged the compliment paid him,—

An interesting communication was read by Mr. Cramb, of Glasgow, on the albumen process, in which he detailed the modifications which he had found most successful, and exhibited a number of specimens which were much admired.

Mr. Tunny, in a few remarks, proposed a vote of thanks to Mr. Cramb; and, after the usual compliment to the Chairman, the meeting adjourned.

We understand that Mr. Claudet was entertainted at dinner on Wednesday evening by the council of the society.

Photographic Notes and Queries.

Halation.

Sir,—Your theory as to the cause of this phenomenon, though ingenious, does not seem to me altogether satisfactory. Why the mere contact of free nitrate of silver, which cannot be reduced directly by the developer, with particles of silver in the act of reduction, should be sufficient to cause the reduction of the former, is not quite clear. Moreover, if the free nitrate on the dark parts is actually "*swept*" by the developer on to the light parts, as you suggest, surely this *sweeping* would often be in one direction only, whereas the effect described is always equally distinct all round.

Are there any objections to the following supposition? A considerable portion of the rays falling on the lens from a bright point is, of course, scattered in all directions. Some rays are scattered through the lens, and of these, possibly, many are not much deflected from the true course of the properly refracted rays. If this be the case, what is called Halation would undoubtedly take place.—I am, sir, your obedient servant, Reflector.

[The theory we put forward was simply offered for consideration, and we still think the cause specified acts as we indicated. We think it possible, however, as we before stated, that a variety of causes produce results more or less similar. Our correspondent's theory may be true of some cases, but we do not think it is the explanation of halation proper.—Ed.]

Sir,—I cannot believe that your theory of halation is the correct one, and I think the following simple experiment would prove it to be erroneous.

Let a photograph be taken of a subject liable to give rise to the fault in question, and let the developer be poured on, always on one end of the plate, and run off at the other. Then if your theory be correct, the edge of the subject nearest the point where the developer is applied should be free from mistiness; for to it there would be no flow of nitrate from the image, but the edge furthest away would alone suffer, since from it the nitrate would flow partially decomposed from contagion with the nitrate acted on by the light.

Now this, I think, would not be the case, but the halo would be perceptible on both sides alike.

The appearance of the phenomenon would suggest that it arose from the same cause which makes the sun appear blurred and indistinct to the eye when a candle gives a clear and defined image.

Does not Mr. Malone confuse fogging with halation?—Yours, &c., F.

[It is simply because we have most frequently observed the halation in the direction of the flow of the developer that we are confirmed in our opinion of the cause. We think Mr. Malone is too old a photographer and too acute an observer to confound halation with fogging.—Ed.]

Stereo Exchange Club.

Dear Sir,—I have been in the Stereoscopic Exchange Club since the second list of same was published, and though I have received some of the worst stereograms I ever saw, yet on the whole I am immensely pleased with it, for the majority of pictures are as good as my own, and some, very much better. So one good lot makes up for several bad ones.

My object in troubling you to-day is, to impress upon you the necessity of immediately publishing a new list of names. I think that all old members who wish to continue in the Club. should send in their names to be put in the new list; but I do not see the necessity for them to forward you specimens a second time. The latter point could be left for you to decide. The reason why I recommend the plan I have mentioned is, that I have sent stereograms to many of the old members from whom I have received no reply whatever (I now refer to the members on the oldest list), while some have returned my stereograms, saying they have retired from the Exchange Club, others have left the country, and so on.

As the printing season is now advancing, it would be a good time to publish a new list: and if you think that old members should send in their specimen prints again, I shall be the first to do so.

Trusting you will give notice in your next impression of a new list, and thanking you for the trouble you have taken in forming so enjoyable an association as the Stereo Exchange Club, I am, dear sir, yours truly, Isaac Hollis, jun.

In my letter I have given no names, but can do so if desired.

[We shall have pleasure in publishing a new list of names, if those gentlemen desirous of being included will communicate with us.—Ed.]

Cheap Printing.

Sir,—In your impression of April 5th, you answer a correspondent thus, "*For printing card portraits about one shilling a dozen is, we believe, a common price.*"

Now if such is the case, we may depend upon it, there is something common, very common, to be obtained in return.

The above remark coming from such an authority as yourself, is, unquestionebly calculated to prejudice the interests of photographic printers of integrity, unless they receive your support in return.

As an old photographer, and one well versed in the difficulties and annoyances in connection with printing for the profession, I say emphatically (and all good men and true will coincide with me) that *no one* can print upon such terms, and do justice to themselves and those that employ them.

By way of caution to those persons fond of making the "market penny," I hand you the following sketch.

Some time ago, a certain publisher having negatives of popular interest, gave them to a *remarkably cheap printer*, and in due time received the copies from them. When canvassing the dealers to purchase his goods, what was his dismay to behold his own subjects in the market, and selling at a price less than he could supply them for!

This, sir, is my simple story; if you can afford space, I trust you will give it a place in your pages; for whilst you are ever ready to give advice to those asking for information, I feel confident you will as readily uphold the interests of those who earn their bread and butter by the sun. I am, sir, yours respectfully, A Printer's Devil.

London, April 10th, 1861.

[Our correspondent only does us justice in crediting us with the desire to maintain fair prices in every department of photography. We believe that a tendency to miscalled cheapness in every branch, has been the bane of the art, and the ruin of the profession. Low-priced lenses, low-priced cameras, low-priced chemicals, low-priced pictures, are all monstrous mistakes. We quoted the price on the authority of one well versed in the matter, but we may have misunderstood him. These are things that, without direct inquiry, we cannot know, as we are not engaged commercially in photographic printing. We will inquire further. Ed.]

Strengthening Negatives.

Mr. Brothers writes to say that the formula for strengthening negatives given in his letter last week may mislead from being stated in grains. It should have been stated in ounces, thus:

Bichloride of mercury	1 oz.
Hydrochlorate of ammonia	1 oz.
Water	20 oz.

The issue is the same; but the above quantities are most suitable for preparing at once.

Transferring Positives.

Dear Sir,—Allow me to correct an error in the recipe for transferring positives to paper, which you kindly inserted at page 371, No. 117, of the Photographic News. I cannot at this moment recollect whether I made the mistake in writing out the recipe, most probably I did.

In No. 117, it stands—		It ought to be—	
Borax ...	... 1 drachm	Borax ...	... 1 drachm
Shellac ...	... 1 drachm	Shellac	... 4 drachms
Water ...	... 5 ounces	Water ...	... 1 ounce

I am, dear sir, yours faithfully,

H. R. Spearman, 91st Regt.

Kamptee, India, Feb. 18, 1861.

Correspondence.

FOREIGN SCIENCE.

[from our special correspondent.]

Paris, 10th April, 1861.

The "Paraffine Process," which made a stir some time ago, and which seems so have fallen into unmerited neglect, has found an advocate in M. Civiale, one of our most eminent photographers. At the last meeting of our Society, this gentleman exhibited two proofs, positives obtained from negatives on paper prepared with paraffine. This substance is found to be very efficacious; the paper prepared with it is perfectly white and transparent, and prints rapidly. The same baths as are employed for ordinary waxed-paper, answer for that prepared with paraffine. The only modifications required are to place the paper, after exposure in the camera, on the sensitizing bath of aceto-nitrate of silver, before immersion in the gallic acid. The time of exposure is about the same as that required for wet collodion.

Our Photographic Society appointed a committee to examine and report upon M. Fargier's carbon process, the details of which I gave you in my last. The committee consisted of MM. Aguado, Bayard, Davanne and Girard, names well known to you. All the details of the process were gone into in their presence, and although the day was rainy, and other unfavourable circumstances interfered with the operations, yet the results were perfectly successful, and satisfactory to the committee. M. Davanne remarks that the only difficulty in the process arises at the moment when the layer of collodion floats in the water, and is to be transferred to the gelatine paper. But he is of opinion that a very little practice will render this feature easy of execution. Placing a glass plate at the bottom of the dish, if the latter be uneven, will facilitate the operation by lifting it under the gelatine paper until the latter meets the collodion film.

The introduction of life-sized portraits, consequent upon the use of the solar camera, creates a demand upon the photographers' ingenuity to provide a means of preparing the paper which is required to be of such unusual dimensions. It is obvious that all our old appliances are inadequate to the purposes of salting and sensitizing. Mr. Henry Romberg has constructed an apparatus for preparing these large sheets of paper, which I will endeavour to describe to you. First, a frame is constructed, say six or seven feet in height, fitted into a broad base, so that it will stand alone; this is fitted with two varnished wooden cylindrical rollers, one near the top of the frame, and adjustable, the other near the bottom, but just above a trough containing the salting or sensitizing solution, which is easily removable. This lower cylinder is furnished with a crank handle. The sheet of paper is passed over the rollers, and then the two ends are fastened together with some insoluble glue, so as to form an endless web. The solution must fill the trough, but, for the salting and silvering operations, the lower cylinder must be so arranged that the *surface* of the paper only passes over the solution. For the other solutions, and for washing the cylinders will, of course require to be changed. By turning the crank of the lower cylinder the sheet of paper revolves, and every part of it passes successively over the surface of the solution, or into it if required. The quantity of solution necessary is reduced to a minimum, and all risk of bubbles on the surface is avoided. Arrangements must be made to keep the solutions in the trough at the same level, but this, and all other conditions necessary to successful operations, will suggest themselves to any ingenious person.

A fact throwing considerable light on the propagation of contagious miasma has recently been made by Dr. Eiselt, of Prague. In the Foundling Hospital at Repy, out of 250 children, between the ages of 6 and 10 years, 92 cases of blennorrhœa of the ocular conjunctiva occurred. This epidemic ophthalmia fully convinced Dr. Eiselt that the contagion was transmitted by other means than by contact. The doctor ordered the nurses to carefully avoid touching the eyes of the afflicted children, and he was no less careful himself; but, notwithstanding every precaution, both the doctor and the nurses were attacked with the disease. Dr. Eiselt then thought of examining the atmosphere of one of the wards of the hospital containing many patients, by means of M. Pouchet's æroscope, and in the first portion of air that passed into the instrument he distinctly recognised small pus cells, which certainly served as vehicles of contagion. The great importance of this discovery has induced many eminent physicians to unite in the investigation of the subject, from which important results may be anticipated.

M. Babinet has made a very original and interesting communication upon a particular point in the physics of the earth; the secular variations in the saltness of the seas; and the possibility of acclimatizing in fresh-water lakes animals which it has been supposed could live only in salt or sea-water. Originally, the waters of the ocean were much salter than they are at present, their saltness has progressively diminished, and this continual diminution is caused principally by the fresh-water brought down by rivers and streams. The degree of saltness of the Black Sea is now expressed by the number 14, one half the number, 28, which corresponds to the ocean. Other seas are even much less salt. The waters of inland seas generally, which are not in direct communication with the ocean, and which continually receive the water of rivers and streams, are very slightly salted. The Mediterranean Sea, on the contrary, to which an inferior current brings continually, by the Straits of Gibraltar, a supply of water from the Atlantic Ocean, has almost preserved its original saltness. Certain internal seas, or great lakes, also, formerly communicating with the ocean, but which have been separated from it by upheaval of earth, have lost their saltness. Lake Baikal, for instance, formerly a salt lake, is now full of fresh water. As the saltness disappeared but slowly, marine animals and plants have passed gradually through successive generations, from a regime of salt to a regime of fresh water, undergoing a complete acclimation. Thus, in Lake Baikal there are found four large species of marine creatures: 1st, herrings in great quantity, which are salted and dried, and exported to distant places; 2nd, seals, exactly like those of the North Seas; 3rd, sponges, whose natural country is the warm and salt water of certain seas; lastly, coral, which we are accustomed to seek only in the waters of the Mediterranean. These premises established, M. Babinet arrives at his principal theme. Since the herring, the seal, sponges, and coral live acclimated in the fresh waters of Lake Baikal, why can they not be introduced, and made to thrive, in the lakes of Savoy, Switzerland, Enghien, the Bois de Boulogne, &c. Nothing could be more easy at the present day than to convey a supply by railway from Russia, at first from Lake Baikal, or other similar lakes of Eastern or Southern Russia.

ART TEACHING FOR PHOTOGRAPHERS.

Dear Sir,—I remember how puzzled and disheartened I once was when after repeatedly shouting some information into the ear of a dear, old, deaf friend of mine, he replied to each such attempt with "Oh, yes, that's all very true; but, you see, what I want to know is,—" and then proceeding to repeat over again the very query I had just answered. I must confess that I experienced very similar feelings when I read the letter from "One in Search of Art Knowledge." Here was poor I, fondly flattering myself that I had been particularly explicit and practical, saying, now and then, after carefully re-reading some article I had just written, "yes, I think that must be easily understood;" and *there* was a sensible, and seemingly earnest, student of photographic art reading, as it appears, all I wrote without at all understanding its drift or meaning.

The following works will be found useful to "One in Search of Art Knowledge:"—Ruskin's "Elements of Drawing," Frank Howard's "Sketcher's Manual," Sir J. Reynold's "Discourses," Windsor and Newton's shilling series of Handbooks, and Burnet on "Composition;" but all these works being written more particularly for the painter, very much that is useless and uninteresting to the photographer will be found in them.

I must own that this fact is somewhat humiliating, but as I am anxious only to be of real use to my readers, will "One in Search of Art Knowledge" favour me by pointing out in what way I can be more practically useful to himself and others.—I am, dear sir, yours, &c., A. H. Wall.

28, *Old Bond Street, W.*

Artificial Silver.—Some years ago Mr. R. W. Fox, of Falmouth, astonished the scientific world by shewing specimens of artificial copper produced by electricity! We now hear of a German chemist who produces silver, sterling silver, not German, by artificial means, at a cost of about three shillings an ounce. We hear moreover that a snug company is forming to work the discovery on a profitable scale: the appliances required are certain chemical preparations, and galvanic apparatus of sufficient power to act on them. Should the experiment succeed on the large scale the profit will certainly be handsome, and additional weight will attach to the opinion, that all metals are resolvable into two or three elements.—*Chambers' Edinburgh Journal.*

Talk in the Studio.

Photography on the Railway.—The *Scientific American* states, that on the Chicago and Milwaukie Railway a very beautiful application of the photographic art is used on the "season passes" and "commutation tickets" to prevent their illegal transfer. When a person applies for a season pass or ticket, he incloses his photograph taken on a small gummed label, and this is pasted on the card which he receives. The conductor of the train can thus see at a glance whether the bearer of a pass or ticket carries the evidence of "the right man being in the right place."

Gigantic Negatives.—The *American Journal of Photography* states that Mr. Whipple, of Boston, has been taking glass negatives five feet by four feet in size.

Photographic Enamels on Glass.—The *Athenæum*, speaking of Mr. Joubert's method of enamelling, says:—By this process we have before us several examples of admirable and perfect transfers of elaborate views of natural localities indelibly fixed on to the glass itself,—defying time and weather, if fixed in the open air,—which may be cleaned as readily as a common window-pane,—do not interfere with the transmission of light to any marked degree,—whilst employed as such, they effectually serve the purpose of shutting out disagreeable views,—miseries we are subject to in London, in such situations as staircase-windows and the like. Fixed in the sashes of a library, these ornaments would give a great repose and exclude external sights; and, judiciously selected by the inhabitant, might fitly sustain the character of the apartment, by presenting views of famous localities or portraits of famous men. What an imperishable gallery of friends' likenesses might not a man gather upon his window-panes! what elegant and appropriate fittings for the glass shelves of his choice book-case! No doubt this process may be as admirably applied to other purposes; but, as it is, the power of getting a photograph of one's own transferred to glass for a trifle, and without risk, is really an enviable one. By the side of the hall-door, how much better these than the poor, common-place ground-glass, or even the etched glass that is now so much in vogue! How applicable to a summer-house, or the lower panes of a conservatory these may be, we need not say.

Photographing State Documents.—Mr. Gladstone, a short time ago, consulted Sir Henry James on the possibility of copying out ancient records by means of his process of photozincography. A small deed of the date of Edward the First was copied and printed, with so much success, and at so trifling an expense, that Lord Herbert of Lea, the Secretary-at-War, ordered the impressions to be bound up with the yearly report on the Ordnance Survey. Thus encouraged, Sir Henry James got permission from the Lords of the Treasury to copy that part of the Domesday Book which relates to Cornwall, as an experiment. He has now achieved this commission, with a result which should certainly encourage the further prosecution of the design, county by county, as appears to have been originally proposed by him. Those who care to have no more of Domesday Book on their shelves than relates to their own shire, can buy the local part. Those who wish to have the whole can bind the several parts into volumes. The work is to be published at cost price, or nearly so.—*Athenæum*.

Abundance of Silver.—*Chemicus*, and another correspondent writing to the *Times*, state that the recent discovery of oxide of silver in a natural state, a thing which, until recently, was believed not to exist, will produce a yield of silver absolutely enormous in relation to that which has hitherto been obtained from the ordinary metallic silver deposits. In a ton of ore, in its natural state, where the normal yield would be 13 ounces, the new discovery will produce an average yield of 113 ounces, the 100 ounces being produced from what has hitherto been regarded as useless. The importance to our mines, where silver is often found near to copper and other metals, will be very great; and in some cases, where the deposit is great and unmixed with other metals, the returns will be almost fabulous, while the cost of working will be absolutely trifling.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St. Martin's-le-Grand.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32 Paternoster-Row.

To Correspondents.

TO AGENTS AND SUBSCRIBERS.

The proprietors of the Photographic News will esteem it a favour if agents or subscribers who may have copies of the following back numbers of the News which they can spare will forward them to the office, 32 Paternoster Row, for which they will receive cash or copies of the current number. The numbers required are: 6, 9, 24, 26, 30, 40, 41, 49. Single copies will be valuable.

J. H.—Use protosulphate of iron as a developer, if you want silvery whites in your glass positives. We do not like the effect of sulphuric acid in the developer, so far as we have tried it. About half-a-minim or a minim of nitric acid is sometimes an improvement. Cyanide is better for fixing positives than hypo, a purer whiter tone being produced.

K. C.—Becoming a private pupil of Mr. Sutton, at King's College will be most likely to meet your wants. You will then not only have first-rate theoretical and practical tuition, but you will also have regular access to an excellent laboratory for practice.

Inquirer.—The word superposition is used in relation to transparencies in contradistinction to camera-printing. It means that a negative is placed upon a dry sensitive plate and exposed to light as in ordinary printing. In camera-printing the wet process is used. The negative is placed in a cell or groove at a proper distance from the camera and lens and the light made to pass through the negative to the lens so as to form an image on the ground glass. The use of two cameras is an excellent and simple plan of camera printing. The lens in one camera is placed with the hood through the aperture in the front of the other, from which the lens has been removed. The negative is then placed in the groove in place of the ground glass of one, and the image is focussed on the ground glass of the other. The operations then are all in the usual way.

J. H.—There are various houses who supply the photographic scraps and wafers, but the only one we can recall at this moment is Ayling, New Oxford Street. For the wholesale supply of card portraits, Marion, Regent Street; McLean and Melhuish, Haymarket; and others.

R. N.—To enlarge a picture 6 in. by 4 in. to 14 by 12 in. with a lens of 4 in. focus, the negative must be placed about 5½ inches from the lens, and the camera extended about 14 inches. We speak in round numbers, but you will perceive, as the enlargement is in linear proportion, a 6 by 4 negative could not be enlarged to just 14 by 12, neither more nor less, as the relation of 6 to 4 is very different from that of 14 to 12. As you will have to enlarge at two operations, in the first of which you will obtain a transparent positive, do not attempt to take this on waxed paper as you propose, as a waxed paper picture is altogether unsuitable for printing by transmitted light in the camera. Take the transparent positive on collodion, and from that you can take a negative on waxed paper. The necessary amount of exposure must in all cases be ascertained by experience, as so many circumstances will affect the question. You will find a table of distances for enlargement in the Photographic Almanac. There is a good deal of information on the subject scattered over the pages of the News, we may mention particularly at p. 189, vol. 1, (No. 15); p. 111 and p. 158 vol. 4, (Nos. 96 and 99).

J. C. B——d should let us have his address that we may be in a position to communicate with him if necessary.

M. M.—The spots you describe are probably sulphur spots. A correspondent the other day sent us a glass positive covered with small black spots, which, on examination, proved to be sulphide of silver. A very common source is the using of a vulcanized india-rubber blower for removing the superfluous colour in tinting.

Focus.—A view lens should never be used with the full aperture.

X. Y.—If you tone with acid chloride of gold, and place the print unwashed in hypo, you will undoubtedly get more or less of sulphur toning as well.

X. Y, Z.—We prefer the binocular stereoscopic camera for our own use for a variety of reasons. No. V1 decidedly. If you send us your address, we can give you fuller information.

J. B., Aberdeen.—We have not personally tried either of the lenses you name, but have seen good work done by both. We will make some further inquiry, and let you know.

Noaval.—Acklands "How to take stereoscopic pictures," published by Horne and Thornthwaite, will give you information as regards the use of a single-lens camera; the use of the bi-lens camera does not need explanation. Two thicknesses of good yellow calico may serve for a tent if it be not placed in direct sunlight. A good deal depends on the quality of the calico. Many tents are made of two thicknesses of yellow calico and one of black, leaving about a foot square of the yellow only, as a window. Volumes 3 and 4 of the Photographic News are to be had, price 10s. 6d. per vol. Vols. 1 and 2 are out of print.

A. G.—The "white" of eggs is always of a yellow tint, and is deeper in the eggs of some fowls than others. The extremely attenuated layer on albumenized paper, does not perceptibly affect the colour. It is not necessary to decolourise it. In some experiments, some time ago, to increase the limpidity of the albumen, we first added ammonia, and then hydrochloric acid, to form the hydrochlorate of ammonia in that way. This made it limpid as water, but changed the colour to a deep brown. We did not observe that this colour was apparent on the prepared paper.

Sul.—The spots on your positive were undoubtedly from sulphur. We think the vulcanized india-rubber blower the most likely source. Abandon its use for one unvulcanized, and try.

A. B.—The practice of using collodion with seven parts of ether and one of alcohol, is very little followed now. Equal parts of each are very convenient. For negatives we prefer at least 5 grains of soluble cotton to the ounce.

Edward L.—We have used the bellows form of camera for many years, and find no fault of any kind with it. There are other forms of bellows cameras besides Kinnear's, you will find them described in trade catalogues.

B.—The Exhibition of the Photographic Society is closed.

C. F.—Various articles in the Taupenot process have appeared in the News, but another will appear shortly.

D. O. F.—Prints on albumenized paper are suitable for colouring in oil. They require preparing with a coating of gelatine or isinglass, to prevent the oil sinking into the paper, and thus drying or "bearing out" irregularly

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 137.—April 19, 1861.

A HINT ON THE METHOD OF DEVELOPMENT.

There is an important hint contained in Mr. Vernon Heath's excellent paper on working wet collodion in the field, which appeared in our pages a fortnight ago, to which we think it desirable to call especial attention.

All photographers are familiar with the fact that one of the troubles in working large plates successfully, arises out of the difficulty at times experienced in getting the developer to flow over the plate in one sweep, without any stoppage or tendency to run in greasy lines; and that unless the plate be so covered at once, stains and lines on the negative are the inevitable result, from irregular development. Mr. Heath's method entirely obviates this difficulty: instead of applying the developing solution direct to the film after exposure, he applies first sufficient distilled water to cover the plate; and after allowing it to flow backwards and forwards a few times, returns it to the developing cup, and there adds a portion of developing solution which he then applies to the plate. After bringing out the details with this dilute developer, he proceeds to obtain sufficient intensity by means of a stronger solution.

Mr. Heath's especial object in using this method is to obtain an amount of detail and softness by the slow and gradual development, not to be acquired by a more rapid and sudden reduction. He also remarks that in hot weather a great advantage is obtained in the development being quite under control.

As we have remarked, there is another advantage, to which Mr. Heath has not adverted, the entire immunity from stains caused by the irregular flow of the developer. In the use of iron as a negative developer, this advantage will be of great importance, as an almost insuperable difficulty in using it for large plates has arisen out of the difficulty in getting the plate covered with sufficient rapidity and evenness to prevent irregular development, without a very weak iron solution and full amount of acid. On adopting this method, however, all difficulties of this kind vanish. It is only necessary to have a solution of iron of, say, double the strength intended to be used; and instead of applying it at once, first cover the plate with distilled water, letting it flow backwards and forwards until it is all thoroughly mingled with the free nitrate, and there are no more greasy lines; pour it back into the developing cup, and add to it an equal measure of the strong iron solution, which may then be applied to the plate without danger of any irregularity or stoppage in its flow, or consequent stains or markings in the development. No fear need be entertained of any immediate reduction on mixing the iron developer with the dilute nitrate of silver solution which has been poured off the plate. If the iron solution contain an average amount of acid, whether acetic acid or citric acid be used, and the nitrate bath be in anything like a good working condition, no immediate decomposition takes place on adding the iron solution to the dilute silver solution. We have tried this method with complete success, a gradual, delicate, and perfectly clean development being the legitimate result. No alcohol need, of course, be added to the developing solution, as its only office being to aid in the ready flow of the solution. it is not only not needed here, but would be positively injurious.

SUBSTITUTE FOR NITRATE OF SILVER.

Some few months ago the somewhat startling announcement was made in the French scientific journals, and translated from thence into our own and some other English journals, that a substitute for nitrate of silver had been discovered, and named Photographic Ink "*Encre Photographique; remplaçant le bain d'argent.*" Certainty of execution, permanency of result, and a large economy in cost were the attractive recommendations which distinguished this "compound salt." These and other advantages guaranteed by the avowed conviction of eminent men of science such as the Abbe Moigne, and of first-rate practical photographers like Disderi, were sufficient to arouse the interest of others besides the scientific *gobemouche*, and arrest the attention of the most incredulous. The new product was at once patented both in France and other countries, and in France a "*Société des Encres Photographiques*" was established for its manufacture and sale.

Unfortunately, however, trial of this substitute did not fulfil the hopes held out, and analysis seemed to indicate that the "ink" simply consisted of adulterated nitrate of silver. The specification of the patent—which has not been completed, the invention having only received provisional protection—has recently been published, and from it we learn that the "substitute for nitrate of silver" replaces that salt much in the same way that sand is said sometimes in the hands of the dishonest grocer to replace sugar, sloe-leaves to replace tea, and chicory to replace coffee; in short that the invention simply consists in an adulteration of the nitrate of silver. Here is the specification:—

"I Louis Cyrus Macaire, of Paris, in the Empire of France, Artist, do hereby declare the nature of the said Invention for 'A Substitute for Nitrate of Silver, particularly applicable to Photographic Purposes,' to be as follows:—

"In forming my substitute for nitrate of silver, I propose using, in combination with the pure silver and nitric acid now employed, certain quantities of azotate of potash and a small portion of a baser metal, such as copper, tin, zinc, or bismuth. These materials mixed in the proportions below mentioned I have found to answer well:—

Pure silver	... ...	1·
Nitric acid	... ...	1·50
Azotate of potash	...	1·50
Zinc or other metal	...	·1
This combination producing		4·1."

Voila tout!

"INSTANTANEOUS PHOTOGRAPHY, WITHOUT COLLODION, WITHOUT NITRATE OF SILVER, AND WITHOUT DEVELOPMENT."

The very excellent journal recently established by Herr Liesegang and M. Lacan, *Le Moniteur de la Photographie*, contains in the review of the month, in the last number, the announcement we have quoted above; and we see that M. Lacan, in his interesting letter to our Liverpool contemporary, repeats the paragraph to which this announcement refers. He states that a good deal of attention has recently been given in Paris to the process published in England by Mr. Bellini, in which a mixture of shellac and gum sandrach in ether and alcohol, to which are added iodide, bromide, and lactate of silver, and also iodide of iron, is stated to give an almost instantaneous picture without development.

Now as the announcement of such a process was originally published in our pages, some six months ago, under the head, "Startling Announcement," we feel bound to tell what we know on the subject, lest, appearing with such respectable indorsement, some readers of the *Moniteur* or *British Journal* may be misled by it.

We found at our office on a Thursday in September of last year, a few hours before going to press, a letter from Mr. Bellini making the announcement already referred to. The statements were startling; but so was photography itself a few years ago: we resolved, however, before inserting it, to see the writer of the letter. We did so; but it was evening, and there was no opportunity for verification of the statements; but we were shown a number of specimens, which looked uncommonly like collodion positives, but which were stated to be the result of this process. We were invited to see a picture taken by the process at our earliest convenience; but in the meantime urged to insert the letter, to establish priority of discovery at once. As the gentleman, who was entirely unknown to us, seemed to make his assertions in perfect good faith, we inserted the letter, which will be found in the 250th page of our fourth volume, and added at the same time that our readers must take it for what it was worth.

We called repeatedly on Mr. Bellini to witness his process in operation; but on each occasion something was wrong. The chemist had supplied him with the wrong article; the preparation was too newly mixed; the light was not suitable,—in short, we never saw anything done. Once or twice an attempt was made, but no result worth mentioning followed; and we finally lost sight of Mr. Bellini, who changed his address.

If any of our French brethren have succeeded better we shall be glad to hear of it; but we feel bound to mention these particulars in order that those photographers who are what Mr. Thomas once described as "afflicted with an experimental turn of mind," may know exactly what grounds they have for further investigation.

THIRD REPORT OF THE EXPERIMENTAL COMMITTEE OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

In this report the Committee do not aim at exhausting the subject of dry plate photography. They propose only to report on those which they consider available for general out-door photography.

During the coming season it is their intention practically to test these different processes, one against the other, to a greater extent than the nature of the weather has hitherto enabled them. In the mean time they place before the Society the result of their investigations so far in the several processes following.

The Taupenot; or, Original Collodio-Albumen Process.

This process, on the whole, is considered an exceedingly satisfactory one, although there are certain difficulties attending it, which will ever prevent its becoming a general favorite with the amateur.

Particulars of Manipulation.—Sensitize in the ordinary manner, using any collodion, provided it is not too thick, and *thoroughly* wash under a stream of running water. It is not necessary to use distilled water for this purpose. Iodized albumen is now to be poured over the washed collodion surface. This albumen is prepared as follows:—

Albumen	1 ounce
Water	¼ „
Iodide of potassium...	5 grains
Bromide of potassium	1 „
Ammonia	10 minims

Dissolve the iodide and bromide in the water, then add the ammonia. Mix altogether with the albumen, and beat the whole into a froth and allow to settle, when the clear portion may be poured into a stock-bottle for use.

Air bubbles must be carefully avoided, and the excess of the portion of albumen taken from each plate should not be returned to the stock-bottle, but placed in a separate receptacle for future use. It should not, however, be used more than two or three times, as after that it becomes too dilute. Allow the plate to drain on one corner five or ten minutes; then dry rapidly before a clear bright fire, and make it quite hot. This tends to prevent blistering in development.

In this state the plates are insensitive to light, and may be kept for years. This keeping quality is very convenient, as it enables the photographer to prepare, during the winter months, a stock for the summer season.

To sensitize these plates, immerse them in aceto-nitrate of silver, prepared as follows:—

Nitrate of silver	40 grains
Acetic acid	½ drachm
Water	1 ounce

and again thoroughly wash. The amount of washing, however great, seems to lessen the sensitiveness, but adds to its keeping qualities.

Development is best effected with gallic acid. Place it, face upwards, in a dish, with sufficient of a saturated solution of the gallic acid to cover it. When it has remained five or ten minutes, add a few drops of silver solution, and mix well in the dish; the picture will gradually appear. When all the details are out, add more silver till the development is complete. Fix in hyposulphite of soda.

The above method of manipulating is that followed by Mr. Mudd. Your presentation print of this year is a proof that in such hands as his the process leaves but little to be desired.

Those members of the Committee who have given the process a fair trial are of opinion that it is uniform and certain in its results, and possesses many advantages peculiarly its own, not the least of which is the allowing of long exposure to bring out detail in the shadows, without fear that the more strongly-lighted parts will be overdone. It permits of the ready removal of stains during development, the film being so hard that a camel-hair brush may be used for that purpose.

On the other hand, the use of the second bath involves considerable additional trouble; the plates, unless carefully prepared, are liable to blistering of the film; and, after the final sensitizing, their keeping properties are limited. This latter inconvenience, however, may be remedied by washing in salt and water, then in plain water, and finally applying tannin and gallic acid to restore intensity. But all this tends further to complicate an already not over simple process.

Nevertheless, to those who do not object to the trouble of preparation, the committee have not the slightest hesitation in recommending the Taupenot process as safe, and, with proper manipulation unsurpassed in its results.

The Fothergill Process.

Of all the dry processes this, perhaps, is in more general use than any other. Its simplicity and certainty, particularly for small plates, especially recommends it to the amateur.

The following are individual opinions of some of the committee who have been in the habit of adopting this process:—

Mr. Borchert describes it as being "the best process, with *little* washing for highly sensitive plates, with *long* washing for keeping plates of average sensitiveness." Mr. Martin says, "my practice has been confined almost exclusively to Fothergill's original process, with which I have been very successful. I like it for its simplicity, and shall continue to practise it." In Mr. Clark's hands "the process has proved very successful, more so indeed than any other. The exposure is short compared with many other processes."

With some of the committee there appears, however, to be a difficulty in obtaining a surface of uniform sensitiveness and intensity, more particularly with large plates. Mr. Davis says, "The difficulty of obtaining an evenly sensitive film of albumenized nitrate of silver affords a decided impediment to the successful practice of the process." Mr. Hannaford, in order to overcome this difficulty, recommends the use of a second bath of nitrate of silver, of the strength of about five grains to the ounce. The plate when taken from the sensitizing bath is to be thoroughly washed, and then immersed in the weak bath, by which means a more uniform coating of free silver is got on the plate than by the ordinary method of washing with a limited quantity of water, or until greasiness disappears. He also calls attention to the modification of this process, which will be given presently.

Particulars of Manipulation.—Numberless modifications of the Fothergill process have from time to time been given; the Committee, however, prefer the following simple plan which is more generally used than any other, and which is thus described by their colleague, Mr. Clark:—

"The modification I have adopted is that of washing the plate freely after sensitizing, in any quantity of water, until the greasiness entirely disappears. I then pour on one corner of the plate sufficient albumen solution to flow freely over to the other end, this forces the water before it. I then place it on the levelling stand, and pour a second quantity of albumen on, and allow it so to stand while I coat another plate. It is then washed in a large quantity of water and stood to dry. My albumen solution consists of 1 of albumen to 3 of water, and ½ oz. of ammonia to the pint, it is beaten well up, allowed to settle, and decanted; I prefer this to filtration."

This method is similar to that lately described to you by Mr. Howard, in his eminently practical paper read at the February meeting of this Society.

The addition of a chloride, or a citrate, to the albumen is advantageous in certain circumstances, such as of over intensity he complained of, but the above simple plan will be found to give the most charming results.

The following modification of this process has been proposed by Mr. Hannaford.

Mr. Hannaford's Modification of the Fothergill Process.

Many complain that in preparing large plates by the Fothergill process they experience difficulty in obtaining a surface producing equal sensitiveness and intensity throughout. This difficulty I had to a considerable extent got rid of by thoroughly washing on removal from the sensitizing bath, and afterwards redipping in a second bath containing about 5 gr. of silver to the ounce. But this method, evidently involving a multiplicity of operations, and the true beauty of the Fothergill process being its simplicity, I have been induced to make some experiments having for their aim the reducing of the process to as simple a form as possible, so as at the same time to obtain the best results.

These experiments have not been carried to the extent I purpose, and I cannot therefore give the exact formula in the modification I am about to suggest; nevertheless, I trust my remarks will not be without some degree of interest to the society.

The first point to which I directed inquiry was this:—What action ensues on applying the albumen preservative to the partially-washed plate? It is very generally supposed that the free silver remaining on the film is thrown down as an albuminate; and, therefore, as the amount of washing the plate receives, regulates the quantity of this albuminite, thereby affecting the sensitiveness and intensity of the film, we have received various instructions respecting this part of the manipulation ranging from the "four drachm" to the "unlimited."

Now, it will be found that if we place, say, half an ounce of albumen mixture in a glass, and add a drop or two of our silver bath, the white precipitate at first found is almost immediately redissolved by the ammonia in the solution. The same action ensues on the albumen coming in contact with the free silver on the partially-washed plate. But it is evident that the ammonia becoming weakened by partial saturation, as it flows on over a large surface, its action is not equal at all parts.

Again, following the same line of reasoning, we may consider that as albuminate of silver remains on the plate when finished but while still wet. The film, I think, mechanically retains a part of the albumen, which in its turn mechanically holds a portion of the silver in combination with ammonia. It is possible, however, that the salt may be a double one of ammonia, nitrate of silver, and albuminate of silver. Whatever it is, we no doubt get a soluble, instead of an insoluble salt, and which on evaporation of the ammonia, combines again with the albumen to form albuminate of silver. Thus whilst wet we have the soluble salt, but when dry, so that the ammonia has evaporated, the albuminate of silver is formed in the pores of the film.

Reasoning in this manner, it at once struck me that to form this silver compound in the albumen mixture, would be much neater than obtaining the same thing at random on the film. This I did by adding nitrate of silver as long as the precipitate would dissolve.

In order that you may be enabled, should you desire so to do, to follow out my suggestions, I will give you the plan by which, so far, I have best succeeded:—

Particulars of Manipulation.—To the white of one egg add three ounces of water, and about twelve minims of ammonia. This, well beaten, is the ordinary albumen mixture for the Fothergill plates. Now add silver solution drop by drop, at first a white precipitate is formed, but quickly re-dissolved. Directly, however, this albuminate of silver is no longer so dissolved, cease. The mixture should present a slightly milky appearance, and in this state may be kept some time. Its keeping qualities will, however, be better with the addition of just ammonia enough to re-dissolve the milky precipitate, and in this state, I think, works cleaner than any "mealy" collodion giving good results in the wet state, and after sensitizing *thoroughly*, wash in an unlimited quantity of water. Now pour on the albumen mixture, and allow it to flow over the plate for about a minute. Then again thoroughly wash, and dry.

It is not needful that the albumen should be removed by washing. In this case, the mixture should be quite clear, ammonia being *slightly* in excess. This plan gives all the simplicity which is claimed for the tannin process with its disadvantage of the danger of losing the film. Development of these latter plates is tedious, but the former come out readily and intensify to any desired extent.

Petschler and Mann's Process.

In the hands of the Committee this process has not come up to what it at first appearance promised. It is less satisfactory in its results than the Taupenot process, liable in a greater degree to a blistering of the film, and not capable of being exposed to diffused light with impunity when in the "insensitive" state.

The Committee have to thank Mr. Mann for the courteous manner in which he has afforded them information during the course of their experiments.

(*To be continued.*)

Scientific Gossip.

The interest excited by the newly revived spectrum observations (we cannot call them discoveries, since so much has been done years ago in England), increases rather than abates, and the process seems to be destined to take its place permanently amongst the ordinary methods of chemical analysis. Another new element has been discovered by its means by Bunsen. It accompanies cæsium in the mineral water of some German spas, and like that metal is one of the same family as potassium, sodium, and lithium. The spectrum of the new metal consists of two splendid red lines situated beyond the red line Kα in the ultra red portion of the solar spectrum. Hence it has been proposed to call the new metal *Rubidium.*

Whilst we are anxious to do full credit to continental discoverers in this new branch of physical optics, we must not forget that much, very much of what is now put forward as new, has been already observed in England. A few weeks ago we drew attention to Professor Wheatstone's discoveries of the spectra of the magnetic spark from different metals. We propose now to draw attention to some notes of experiments which Mr. Fox Talbot has made on artificial spectra. In a paper which he published in 1834 he drew attention to the advantage of employing spectrum analysis for the purpose of distinguishing between strontium and lithium, each of which is remarkable for the fine red tint which it communicates to flame. It is difficult to distinguish between these bodies with the unassisted eye, but Mr. Talbot found that the prism displayed between them the most marked distinction that could be imagined. The strontia flame exhibits a great number of red rays well separated from each other by dark intervals, not to mention an orange, and a very definite bright blue ray. The lithia exhibits one single red ray. The author thereupon proceeds to say that he does not hesitate to say that optical analysis can distinguish the minutest portion of these two substances from each other with as much certainty as, if not more than, any other known method.

The same gentleman has also recorded some curious observations on the flame of cyanogen, which show that if this gas could be procured at a reasonable price, it would be perhaps the best substance known for the photographer to employ for the purpose of illuminating objects of which copies were required to be taken at night. When the magnificent violet flame of this gas is viewed with a prism in an appropriate apparatus, it presents a very distinct and peculiar character, separating the violet end of the spectrum into three portions, with broad dark intervals between. But the most remarkable fact is this, that the last of these portions is so widely separated from the others as to induce a suspicion that it may be more refracted than any rays in the solar spectrum. Mr. Talbot states that this separated portion has a pale undecided hue; he should hardly have called it violet, were it not situated at the violet end of the spectrum, but to his eye it had a somewhat whitish or greyish appearance.

A gentleman upon whose calculations reliance can be placed, recently stated that every cubic mile of the waters of the Atlantic contained upwards of fifty tons weight of silver, and consequently set experimentally inclined persons at work devising methods of rescuing some of this precious metal from the "vasty deep." Within the last week or two however, the attention of the would-be silver miners in England has been diverted to a new channel, and they are all, on the strength of two mysterious letters which appeared in the *Times*, searching after "oxide of silver," which it is supposed exists in enormous quantities in the refuse from various mining operations. Any fresh and abundant source of this important metal has especial attractions for the photographer, whilst we need not add that the commercial world in general take deep interest in an announcement which, if true, might seriously derange the currency. We have accordingly taken considerable pains to ascertain what foundation there might be for the statement that native oxide of silver had been found in abundance in the neighbourhood of the ordinary silver deposits, and we are sorry to say that there appears very little chance of this report being correct. The plain statement of what was enshrouded in very vague and mysterious language in the original announcement, appears to be this, that certain Cornish gozzans, which, when assayed by one chemist, were reported to contain from 5 to 13 ounces of silver to the ton, when tried by another assayer, were shown to be as rich as from 54 to 216 ounces per ton. This, we believe, embraces all that has been done, and upon this slender foundation the writers assume that the increased amount of silver arises from the silver being present in some mysterious combination with oxygen, forming an "oxide of silver," of, however, such different properties to the ordinary oxide of silver, which photographers are acquainted with, that the usual methods of assay are quite inadequate to detect its presence, and some round-about plan must be adopted to separate its metallic constituent from it. To a chemist such an idea as this is absurd on the face of it. We all know what oxide of silver is. Who that is in the habit of much experimentation with neutral baths, does not keep in some dark corner a little bottle containing a moist dark brown powder called oxide of silver? Now this oxide of silver is one of the most unstable things known, simple exposure to air, light, heat, or the action of rain would at once decompose it with separation of the metal, or cause it to pass into the state of carbonate or chloride, so we can leave it to our readers to judge for themselves how long it is likely that oxide of silver would remain, as such, in so complicated a mixture as "gozzan." The fact is, we believe, that the owner of the property upon which the ore has been discovered, has been agreeably surprised to find that it is richer than the first assays led him to believe; such occurrences as these are far from uncommon. The plentiful Cleveland iron ore was for a long time cast aside as valueless, until some clever metallurgist pointed out to the iron-master upon whose property it occurred, that it contained as good a percentage of iron as many ores which he was bringing to his furnaces from a considerable distance. Another more striking instance occurred in Australia, where immense quantities of the refuse from the quartz-crushing and amalgamating machines were rendered capable of being reworked at a handsome profit by the simple expedient of putting some wood ashes along with the quicksilver in the amalgamator. We are, therefore, quite prepared to admit that silver may be more widely diffused than has hitherto been suspected, and that it may occur in comparatively large quantities in some Cornish minerals, but further than this the evidence will not carry us. It would puzzle the first chemists of the day to settle definitely as to the existence of oxide of silver in a complicated earthy mixture, and we must certainly ask for some particulars of the experiments and train of reasoning, upon which the presence of oxide of silver in a natural state is assumed, before we can admit of its existence.

A patent, which has recently been taken out, will be found to present some points of interest to the photographer. It is by M. F. R. Grumel of Paris, and is for albums for holding collections of photographs; and which may also be used for preserving lithographs, engravings, and other drawings in. Each leaf of this album is formed of three parts or layers, the two outside ones and the middle one are to be of a thickness about equal to the card or cards to be enclosed; the two outside leaves have a portion of their central parts cut out in form a little less than the cards; the middle one having also a portion cut out in the centre but larger than the other two, and having in addition a portion cut away from the bottom. The three are now superimposed, so that the central spaces coincide, and the edges of the three layers are glued or cemented together all round, except where the portion of the middle layer at its bottom edge is cut away. The cards or pictures are now inserted through this bottom opening and pushed up to the central space, the two outside layers with the inner one forming slides and frames for retaining them in their places. Either one or two cards may be inserted. If two, they are placed back to back, so that there will be a face on each side of the leaf. A small piece of cotton or silk attached to one side forms a hinge or substance by which to bind the leaves so as to form a book. Each leaf may also be arranged so as to expose several openings, each holding cards. It will be seen from the above that this is merely the ordinary album, which is now so popular for holding the *carte de visite* photographs. The arrangement has always struck us as being very clumsy, and it certainly should not form the subject of a patent. The plan is so obvious, that we feel sure some hundreds of amateurs had it in general use long before this patent was applied for.

ON THE TESTING OF COLLODION AND PRINTING BATHS.

BY GEORGE DAWSON, M.A.*

In fulfilment of my promise to carry out an extended series of experiments—the results of some of which you already know—I have now the pleasure of laying before you a larger stock of facts, from which I think we shall be able to deduce a considerable amount of useful information.

Through the kindness of Mr. Hughes and of some other

* Read at a meeting of the North London Photographic Association, March 29, 1861.

friends I have been favoured with many specimens of old printing and collodion baths, all of which I have examined with great care on every point which I thought might be useful in the present inquiry. But, in truth, the question, from causes to which I need not particularly refer, has assumed a prominence and importance far beyond its merits.

Practically speaking, I can scarcely fancy a photographer of any standing sitting down quietly every morning to ascertain how much his baths may have lost in strength since yesterday. It cannot be to acquire useful information, but to gratify an idle curiosity; for he knows, or ought to know, the original strength of his solution—he knows that silver is abstracted each time he excites a plate or paper; and experience soon teaches him to estimate this amount pretty nearly. In short, it is the usual rule, I believe, not to cease using a bath so long as it continues to give good results. There are cases when testing may be of use, but they are exceptional, and not of frequent occurrence. Nevertheless, as the question has been raised—what is the best, quickest, and most easily applied method of testing a negative or positive solution, so as that we may be able to tell within a grain or so the strength of the bath with which we are about to operate?—I shall now contribute my mite towards its settlement.

Several plans have been proposed and instruments devised for this purpose, all possessing defects and advantages in a greater or less degree, which I shall examine separately.

1. Specific Gravity Test.—Against this test it has been urged, with great theoretical probability, that the accumulation of light matter in collodion baths and of heavy matter in printing baths renders its indications valueless. This objection is true to some extent, but not nearly so far as is generally supposed. In proof of this I am able to bring forward some potent facts:—Out of fifteen old printing baths sent to me from all parts of the country for analytical investigation, and varying in strength from 49 to 100 grs. nitrate per fluid oz., all—with one remarkable exception, to be referred to more particularly hereafter—showed by the sp. gr. bottle an amount of nitrate of silver exceeding what they really contained only by from 1 to 5 grains. The exact average of excess was 3·45 grains. The nitrate of soda and ammonia varied from ·75 to 6·25 grs., average being 4·85 grs. In some cases there was not sufficient nitrate of soda or ammonia present to account for the high sp. gr., but in all such instances the baths contained free acid, which seemed to have quite as much effect on the test as the presence of the nitrates. In no case did I detect nitrate of baryta.

I cannot vouch for the accuracy of the strength of any solution of pure nitrate of silver, as indicated by its sp. gr. To my knowledge no reliable tables have yet been constructed. My estimate is based on the following rule, which I have made out by experiment. It will be found, I think, correct to within about a grain.

When sp. gr. is 1·052, or under, reject the integer, take the first two places of the decimal as integers, and the third as a decimal, then multiply by 5·75.

Sp. gr. 1·053 to 1·090 multiply by 5·5.
,, 1·090 to 1·160 ,, 5·25.
,, 1·160 to 1·190 ,, 5·2.

For instance, suppose the sp. gr. of the solution to be 1·146, reject the integer 1: taking the first two decimal places 1 and 4 as integers, and the third, viz., 6, as a decimal, we have 14·6; and as by the table 1·146 lies between 1·090 and 1·160, we have to multiply by 5·25—thus $14·6 \times 5·25 = 76·65$ grs. Now, observe, I do not by any means give out this rule as accurate: by a little *easing of the angle* the indications will be sufficiently near for practical purposes. Hereafter, should the subject be considered of sufficient importance, I may, with more time at my disposal, be able to furnish photographers with a more exact and reliable table. Should any one feel disposed to test the present one, he must not suppose that a newly made solution, say of 90 grs. pure nitrate of silver, dissolved in three ozs. of water, will show 30 grs. to the oz.; for the water, by the addition of the nitrate, has expanded to more than 3 fluid ozs., and ought to indicate somewhat less than 29 grs. Nor is this expansion equal by equal increments of nitrate: it increases upwards; and this is the great difficulty which besets us in the construction of these tables. A progressive law of expansion evidently exists, and probably may be ascertained by a few accurate and well-directed experiments. If so, a series of calculations will be all that is necessary for any strength of solution. After all, however correct we may make our tables for pure silver solutions, their accuracy will be sadly disturbed when testing impure materials. Of the fifteen old printing baths submitted to my examination, the fourteen whose averages I have already given seemed to contain extremely little impurity derived from the original nitrate. Probably the free acid they all contained in a greater or less degree may be attributed to that source. But this seems not to have been the case in the exceptional bath. Its sp. gr. $= 1·193 =$ about 100 grs. nitrate of silver to fluid oz.; whereas a correct analysis gave barely 90 grs. silver and 21·5 grs. of other nitrates and organic matter. A large proportion of these 21·5 grs. was nitrate of potash. How this salt could have got into an old printing bath I am at a loss to comprehend, unless introduced originally along with the nitrate of silver.* For such solutions as this, I admit, the sp. gr. test is utterly valueless.

To those, therefore, who may select this method of testing their old baths, I would recommend the use of at least tolerably pure nitrate of silver; the avoidance of chloride of barium, whose atomic weight is very high, as a salt for their paper; and the abstaining from the addition of any extraneous soluble matter: all of which would materially affect the sp. gr., and render any rule of calculation impossible. The temperature should also be taken into account—60° Fahr. being the standard. For every 10° below this, deduct 1 gr., and for every 10° above, add 1 gr. It may also be of importance to know that the blackening of a printing bath from use does not sensibly affect the sp. gr. One, indeed, I had as black as ink, which, after clarification by kaolin, was affected slightly, but not sufficient to alter the sp. gr. to the extent of $\frac{1}{1000}$. The discoloration I attribute entirely to the suspension of very fine undissolved particles of organic matter in the liquid. With these few precautions attended to, and after deducting from 1 to 5 grs. according to the more or less extensive use of the bath, the sp. gr. indication will tell us to within about 1 gr. the actual amount of silver present—sufficiently near, I should think, for all practical purposes.

As respects old collodion baths, this mode of testing is scarcely so reliable. In six specimens subjected to analysis, the error ranged from 2 to 7 grs. all in one direction, viz., *below* the real quantity of nitrate present. I do not think we can fix this error so definitely as in old printing solutions; for, if a collodion bath when not in use be well stoppered or closed up, the error will be greater than if (other conditions being equal) it were left in a warm place, and exposed to the atmosphere. It has been strongly urged that the error may sometimes lie on the other side, and an instance has been produced in proof. I am not by any means sure, but I believe, that one of my seven analysed specimens, was the identical instance adduced. It was contained in a bottle labelled "old collodion bath," had rather a large sediment of flocculent organic matter, and smelt very strongly of stale pickles, masking completely the smell of ether and alcohol, if it contained any. The sp. gr. was 1·065, showing about 36 grs. to the oz.; whereas, by careful analysis, it contained only 26·95 grs. nitrate, and 6·75 grs. foreign matter—a large proportion of the latter being organic. One fluid ounce freed from silver by chloride of sodium required 19 grs. dried carbonate of soda to produce neutrality. The acetic flavour being thus destroyed, the alcohol and ether should now have made themselves perceptible; but they did not, and I doubt whether a trace of either was there. I have therefore no hesitation in saying that this so-called collodion bath was never used for that purpose at all;† or if so, the ether and alcohol it contained, from exposure to the air, or from some other predisposing cause, were converted into acetic acid, which affected the sp. gr. to such a degree.

2. Hydrometer Tester.—To the form of this instrument as sold in the shops some strong objections may be urged. In the first place it is graduated arbitrarily, that is, it does not show the sp. gr., which in some measure would be a check on its correctness. Secondly, the stem is too short, and, in consequence, the scale is crowded into too small compass to enable us to read accurately its indications. In principle it is of course the same as the former method; and when we obtain good sp. gr. tables of pure nitrate of silver solutions, and a better mode of manufacturing the instrument, that it may show clearly on one side of the scale the sp. gr., and on the other the corresponding grains of nitrate, we may hope to see it exten-

* This printing bath, we are informed by Mr. Dawson, was, as he has since ascertained, that of Mr. Macfarlane, of Glasgow.

† This bath was Mr. Bowman's, of Glasgow.

sively used, both on accouut of its approximate truth, and its exceedingly simple mode of application.*

3. Another class of instruments has been devised, depending on a different principle, viz., that 58·5 grs. of chloride of sodium will exactly precipitate 170 grs. nitrate of silver. Theoretically this should give perfectly correct results; and, even practically, with extraordinary precautions and extremely delicate instruments, we may depend on it to within $\frac{1}{300}$ of a grain. But what do we find with theso instrumeuts? We find them in the hands of different individuals, and even of tho same individual, giving very contradictory conclusions—sometimes four or five and even more grains over the mark, and sometimes, but seldomer, as many below. Indeed this is not to bo wondered at when wo consider tho many sources of error common to them all. It is difficult to obtain pure chloride of sodium and to dry it perfectly; for the water is not altogether expelled till it has ceased to crepitato under a strong heat. Our glass measures as usually sold are never accurate; and even were they so their shape aud large surface precludes tho possibility of their being accurately used. Moreover, as respects the instruments themselves, on account of their arbitrary graduation, wo have no very obvious and ready means of ascertaining whether tho error which is sure to exist ought to be laid at their door, or that of tho solution, or both combined. In truth, the error is not constant nor always in the same direction, and cannot, therefore, be allowed for. Nono that I havo seen have any arrangement for the violent agitation necessary for tho complete clarification of tho liquor without waste. Finally, when wo recollect that a possible or rather probable large error in one drachm of nitrate solution has to be multiplied by eight, it is only a matter of wonder that their inaccuracy is not greater. A uico balance of errors may occasionally bring about a happy compromise pretty near the truth, but this must be of very rare occurrence. I havo no hesitation, therefore, in condemning these instruments to tho class of philosophical toys, fit only to amuso a photographic amateur and to waste his solutions on a rainy day.

A fourth method, founded on tho same principle, has been proposed, possessing, however, all the defects of the previous plan, attributable to impure materials and imperfect measures, but avoiding others incident to the instruments themselves. It consists in dissolving in a certain quantity of distilled water puro dried chloride of sodium, sufficient to precipitate one gr. nitrate of silver by one fluid drachm of the solution. Tho relative proportious of water and chloride of sodium may be readily ascertained from the atomic weights of the two salts to be acted on. Since tho combiuing number of chloride of sodium=58·5, and that of nitrato of silver=170, it follows by an easy calculation that 66 grs. chloride to 24 oz. water is about tho right proportion. The mode of applying, and the probable results, of this test will be seen from the following experiments:—

I obtained from threo manufacturing chemists of considerablo repute as many specimons of so-called "pure chloride of sodium," which for convenience we shall call 1, 2, and 3. With each I operated separately on a new solution of nitrate of silver, containing rather over 80 grs. to the ounce. *I used three different sets of measures throughout in all the subsequent operations.* After drying for two hours a portion of No. 1 ou a sand-bath, at a temperature of about 400°, I weighed out 33 grs. and dissolved in 12 oz. distilled water. I mado similar solutions of Nos. 2 and 3. Two fluid drachms of the nitrate, along with the washings of the measure and a little nitric acid, wero now poured iuto an 8-oz. stoppered bottle, and solution No. 1 added to the point of no moro precipitation. I repeated the experiment with 2 or 3, using, as I have said before, different sets of measures. There was a very considerable discrepancy in the results—a solution containing exactly 80·25 grs. being represented by the numbers 78·5, 84, and 86·5 grs. respectively. To what causos are we to attribute so much uncertainty and error? Chiefly to tho utter uufitness of our glass measures for such delicate experiments. For instance, besides their ordinary defects, which must be patent to us all, there is another and very curious source of error not generally known, attributable to the fact that, although our quarts, pints, and ounces are constructed as they ought to be, from the standard of the avoirdupois, our drachms, graduated iuto minims, are made from apothecaries' weight, containing 480 grs. to the ounce. They are, therefore, calculated to contain 60 instead of 54·7 grs. distilled water at the temperature of 60°.

Another modo of testing, which can scarcely be called of practical value to the photographer, but capable, in the hands of one accustomed to chemical manipulation, of great exactitude, is useful when we want to estimate how much foreign matter is present in our old baths, beside nitrate of silver. Its principle is different from tho former, and consists in precipitating the nitrate by puro hydrochloric acid; filtering, washing, and drying the precipitato along with its previously weighed filter, till they cease to lose weight, and then calculating the nitrate from the weight of chloride. The filtrate, with all tho chloride washings, when evaporated to dryness, will show by tho weight of residue, the other uitrates and organic matter which may have been present. A slight error in estimating the silver may occur when operating on a very dark coloured old bath—a small quantity of organic matter (never according to my observation reaching $\frac{1}{4}$ gr.) suspended in the solution being precipitated along with the chlorido detained by the filter, and not got rid of by any amount of washing. But, if we first clarify with dried kaolin, *no* organic matter is thus thrown down.

Having now expressed my opinions and the reasons for the same pretty freely, but necessarily very briefly, on the advantages and disadvantages of tho several testing systems which have come under my notice, I may expect furious attacks from certain interested or over-sensitive parties, who may feel themselves aggrieved by my unbiassed and disinterested expression of opiniou. To such individuals I may beforehand reply—and this is the only reply they may have—that unless they can show error in, and unwarranted deductions from, the facts I have adduced, no notice whatever will be taken of their communicatious. If they show either of these I shall bo glad to retract my opinion for the higher pleasure of gaining a new truth. I have no hesitation then in pronouncing the hydrometer, when properly constructed, and when used with the proper precautions, superior to all the ordinary modes, and perfectly sufficient for the purposes of tho practical photographer.

Should greater nicety be required, I am prepared with a method, or rather a modification of a method—and, indeed, had it incorporated with this paper—by which, without any great trouble or extraordinary manipulations, we can tell within $\frac{1}{60}$ of a grain the amount of silver in any solution. It is the plan I have adopted throughout tho course of my experiments for checking tho analysis by hydrochloric acid, which I was compelled to have recourso to in order to estimate the other nitrates and organic matter. The instruments I used were made by myself; and, in getting moro artistic-looking duplicates mado by Mr. Zambra to show you, an accident occurred which compels mo reluctantly to defer this part of my paper to next meeting, or to consign it to a quiet corner of our Journal.

* Mr. Dawson informs us that he has just completed a very carefully calculated specific gravity table for pure nitrate of silver, ranging from 10 to 140 grains, which will shew that the estimates, by specific gravity hitherto have been rather too high. We hope to publish it shortly.

ON THE FADING OF PHOTOGRAPHIC PRINTS.

BY H. H. SNELLING.*

In my printing operations I have, as I said before, confined myself to no oue formula. I have toned and fixed separately, and have used the toning and fixing solutions together, and I cannot give preforenco to either method so far as permanency is concerned; but as regards clearness, solidity, and delicacy of detail, I consider the mixed bath has decidedly the advantage. In confirmation of this opinion I will present a few illustratious, with the formulas by which some of them were made, going back to the introduction of photographic printing.

I here present to the society one [marked No. 6], of thirty-two prints I received from Mr. Blanquart Evrard, in 1850; made before tho introduction of tho gold-toning process. These prints wero made from paper negatives; glass at that time being very little, if at all, used in France. Eight of the thirty-two proofs I had framed (the rest I gave away), and of these eight not one has exhibited the slightest disposition to fade. For permanency I consider nothing cau be more perfect, and in other respects they are not inferior to photographs of the present day. These pictures have hung for ten years or more on my parlour wall and have been subjected to tho severest tests. The method given for toning and fixing these pictures

* Continued from p. 176.

—in a printod treatise which accompanied the proofs—was as follows:—

Hyposulphito of soda	1 part.
Water	5 or 6 parts.
Nitrate of silver, a fow grains; quantity immaterial.	
Acetic acid, sufficient to give tho desired colour.	

Mr. Evrard also gives instructions for obtaining proofs of any desired tint, from the finest black to the most delicate sepia. A perusal of his work will show that many of tho so-called modern improvements in paper photography were pretty well investigated by this early writer.

No. 7 is a proof made by M. Renard, of Franco, moro than a year later than No. 6, and sent to me as a specimen of tho then new method of toning with chlorido of gold. It will be seen that this picture is fading. Decomposition set in it about two years after it was hung up.

That gold is not essential to the fineness of the print or permanency, is fully proved by these prints. I would also state in confirmation of this fact, that Mr. Turnor recently showed me some prints made some years ago (hyposulphito of soda and chloride of silver being the toning and fixing solution) that are as fresh and perfect as on tho day they wero made.

I will now proceed to somo of tho photographs which have from time to time illustrated my journal. I regret that the formulas for toning and fixing were not always given, but from their having been dono by the various methods spoken of, I am convinced that, with ono or two exceptions, all could have produced permanent photographs, if sufficient caro had been taken in the manipulation.

No. 8, was made by Mr. Whipple, of Boston. Ono thousand impressions of this print wero taken in November 1853, and of those that have come under my observation, not one has faded. In some tho colour has changed in spots from handling with dirty fingers.

No. 9, also by Mr. Whipple. Nearly all of these faded, evidently in consequence of being varnished with gum-arabic and sugar.

No. 10, also by Mr. Whipple. These were varnished, and many of them faded; also No. 13. The majority, however, remain perfect to this day.

No. 11, by Mr. Whipple, although not varnished, have faded more or less, ovidently from having been mounted with sour paste.

No. 12, by Messrs. M'Clees and Germon, of Philadelphia, exhibit, thus far, no ovidences of fading.

No. 14, by Messrs. Masury and Silsbee, of Boston. These were undoubtedly toned in a lead bath, and are varnished, yet I have seen none that have faded.

No. 15, by Messrs. Richards and Betts, of Philadelphia; all these, so far as I have seen, have remained as they were delivered to this day.

No. 16, by Mr. Whipple, and varnished, all faded.

No. 17, by Messrs. Richards and Betts, havo all faded, as seen in the samples, undoubtedly from improper toning.

Nos. 18 and 19 are the pictures mentioned by Mr. Seely at one of our meetings last year, as having been printed by himself, and in illustration of tho permanency of tho method he advocates. Many having faded, as shown by one of the prints hero given, the validity of my objection to his theory is mado manifest. This will be further proved.

In the specimens which follow, the formulas for taking which will be given, I can refer the fading in every instance, except one (No. 29) to unskilful manipulation, rather than to the nature of the bath. In nearly all, some prints havo remained perfect under all circumstances, showing that when the *work* was proporly done, tho process was not at fault.

No. 20. A view of the *Palace of Industry* was toned in a bath composed of hypo, salt of gold, chloride of silver, and a few drops of ammonia; and afterwards submitted to a bath of hypo, 1 lb. to the gallon of water. All these pictures faded where the colour was pushed to the black.

No. 21. *A Group*, by Mr. Hayward, of Boston. In salting the paper for this picture, one grain of gelatine to the ounce was mixed with the solution; it was sensitized with a thirty-grain solution, and toned and fixed in a bath made of—

Hypo soda	1 lb.
Chloride of gold	180 grs.
Chlorido of silver	2 oz.
Chloride of lead	2 oz.
Water	1 gal.

Not one of theso pictures have faded.

No. 22. *Columbia College*. These pictures were first fixed in a bath consisting of water 2 gals., hypo 2 lbs., aqua ammonia 40 drops; and then tonod in, water 2 gals., hypo 2 lbs., acetate of lead 1000 grs., salt 1000 grs., chlorido of gold 90 grs., chloride of silver 2 oz. Very fow changed evidently from over-toning.

Nos. 23, 24, 25 and 26, were toned in the same way as No. 22. A great many have fadod.

No. 27, was tonod and fixed (without previous washing) in hypo 2 lbs., Burgess gold 12 bottlos, acetate of lea to satura tion. Some of these faded, but tho majority remain perfectly good.

To show the effects of slight modifications in tho toning bath I givo two prints of *Mrs. Mozart*, Nos. 28 and 29. Both wero printed on American gelatinized paper, sensitizod in the usual way; No. 28 fixed in a bath composed as for No. 21.—No. 29 with lemon juice added. Every print toned without the lemon juice remain perfectly good, whilo those toned with it have all faded.

No. 30, Portrait of Mr. Piard, was toned and fixed in the same bath as No. 22, without provious washing; nono have faded.

I would again call attention to the threo prints I presented on a former occasion, Nos. 31, 32, and 33; No. 31 was toned in a bath of hypo and gold. No. 32 in tho same bath, with five drops of a saturated solution of citrate of iron to the pint added. No. 33 in a solution of aqua ammonia, ten drops to the print, only. It will bo perceived that there has been no change in these prints since they wero first exhibited, and I am convinced that a careful series of experiments will determine that we can do without hyposulphite of soda by substituting aqua ammonia and thus render the permanency of the photographic print a certainty.

I have used every modification of the toning bath, and have found that, for permanency, tho less complicated it is the better; that in making it, it is necessary to avoid an excess of any activo ingredient, and when any are in excess to watch the prints closely to avoid undue action.

I have found that proofs printed by diffused light tone better, keep better, and are in every respect finer than those printed in direct sunlight. The longer they aro printing without turning yellow, the more solid and brilliant they will be. Sunlight pictures are the first to fade.

The longer they are arriving at the proper degree of strength under the influence of light, the more toning they will bear without losing the delicate middle tints, the more transparent will be the shadows, and the stronger will be the black without sulphurization.

That it is best never to suffer tho print to pass the purple tint in toning.

That it is impossible to ensuro permanency if more prints are put into the bath than it will float without their touching each other; or if they are suffered to lie still; thoy should be kept constantly in motion. Nor is it possible when spongy paper is used.

Finally, every possible caro should be taken in every part of the process, from tho first handling of the paper to the mounting of the print. Filter all the water beforo and after making your solutions, and your toning bath every day, if a large number of proofs are daily made, and at least every third day if the number is limited. This will enablo you to use up every particle of the toning bath without fear of spoiling any of your prints. Keep everything clean, and keep all vicious chemicals out of the toning room.

They say that "*care will kill a cat*," but rest assurod it can never kill photography, and that the want of it is the main cause of so many photographic failures.

Dictionary of Photography.*

Printing by Development.—The process of printing by development is one of the oldest of the paper processes, being necessarily involved in the principle of the calotype process. From whatever cause, it has never been largely practised, or come into popular use. This is somewhat singular, when it is remembered that during many months of every year, sun-printing is in this climate an impossibility; whilst printing by development may be effected under

* Continued from p 407, vol. iv.

almost any conditions of light. It is cheaper than sun-printing, no gold toning being required, and the exciting solutions used generally contain less silver. It is more permanent, most of the earliest calotype negatives and developed prints being perfectly good at this day. The probable cause why printing by development has not become popular, lies in the quality of prints that have too often been produced by that method, mealy prints, wanting alike in vigour and detail, being unfortunately amongst the common results.

That these are not the legitimate or necessary results of development printing is to us quite manifest from the fact that some of the finest photographs we have seen are developed prints, some by Blanquart Evrard, and others by Mr. Sutton, which have all the qualities of fine engravings. And we think it by no means improbable, that if anything like the same extended and varied attention had been given to the practice of this process which has been given to sun-printing, a much more favourable opinion of its capabilities would have prevailed.

We shall here first give the details as recommended by Mr. Sutton, because we believe no one has experimented so extensively or successfully in this direction, and because we are familiar, from personal observation, with his manipulation.

Amongst English papers the thin Hollingsworth paper is most suitable, and gives black tones and vigorous prints. Of French papers, Canson's thick positive is most suitable, and has a better surface than the English paper. There are two methods of preparing the paper previous to exciting with silver; one by means of iodides, or iodides and bromides, and the other by means of chlorides. The latter method is recommended for general use, because, whilst papers prepared with iodide of silver are more sensitive, that very sensitiveness increases the difficulties, especially to the beginner. An exposure quite insufficient to produce the faintest visible image is sufficient to produce a vigorous picture, where iodide is used, whilst the chlorided paper permits exposure sufficient for the eye to perceive satisfactorily a definite amount of darkening, in order to produce, on development, the desired results.

To salt the paper, which must, as in all printing processes, be first marked on the smooth side, take—

Chloride of sodium	8 grs.
Distilled water	1 oz.

Immerse the sheets for a few minutes and then dry. If the Canson paper be used, Mr. Sutton recommends the addition of a minim of hydrochloric acid to every two ounces of solution, and allowing the sheets to remain a longer time, so as to neutralize the alkalinity which characterizes that paper.

The silver bath is made as follows:—For Hollingsworth's paper—

Nitrate of silver	30 grs.
Lemon juice	4 minims
Distilled water	1 oz.
For Canson's paper,—	
Nitrate of silver	60 grs.
Lemon juice	8 minims
Distilled water	1 oz.

The chief reason for the disproportion between the strength of the silver baths for the two papers appears to arise from the fact that Hollingsworth's paper is soft and absorbent, and thus becomes sufficiently charged with silver in a weak bath. Great stress is laid on the use of lemon juice and its value in giving vigour to the print. Citric acid, Mr. Sutton states, will not do at all; the natural mucilage of the lemon being required, as well as its acid. The paper is excited by floating, smooth side down, for three or four minutes. It must be hung up to dry in a perfec ly dark room, as the faintest ray of light falling on it now will, on development, produce darkening and injury to the print. It will readily be seen that the latitude as regards the light to which the prepared paper can be exposed, which is often practised in sun-printing, cannot be allowed here.

The time of exposure will of course be regulated by the light, and must be continued until a faint image is perceptible. As the picture cannot be examined by the feeblest white light without injury, it is the best plan to leave sufficient margin exposed to serve for a guide as to the progress of darkening. In bright sunlight two or three minutes, or less, will be sufficient. With a clean good negative, the margins showing a faint tinge of lavender will indicate sufficient depth of printing.

To develope, turn up the edges of the paper all round, pinching them at the corners so as to make the print form a dish, and place it on a plate of clean glass. Now pour in sufficient of a saturated solution of gallic acid to cover the print. Use a glass rod bent into the form of a triangle for the purpose of rapidly spreading it all over the surface, and keeping the solution in motion. In a minute or two the development will commence, and will gradually progress, until, if the exposure has been sufficient, a rich deep black is obtained. The time required for development may be from five minutes to a quarter of an hour, or longer. The colour will pass through various stages of purple and brown, and may be stopped at any point if the print have acquired sufficient vigour. To secure the best effect the development should be carried a little further than appears necessary, as the print will lose a little in fixing.

To fix the print, place it in a bath of hyposulphite of soda, having previously rinsed it from the developing solution. The fixing bath is composed of one ounce of hypo to twenty ounces of water. It should be used fresh; about twenty minutes being sufficient to fix the print. We think that probably a little stronger bath, and shorter immersion might be better. The print will require washing to free it from hypo, as usual.

The tones when the picture is dry are of various gradations, of warm brown and black, and when the operations have been properly performed, have a peculiarly rich and velvet-like effect in the deep shadows.

A soft negative, full of detail, is best for the purpose, as this process has a tendency to give great vigour and contrast to the prints, which degenerate into hardness if very intense negatives are used.

A grain or two of iodide of potassium to each ounce of salting solution gives greater sensitiveness, as we have said, and a variety of purple tones, unalterable with salt alone, are produced in the picture.

Perhaps for use with the solar camera, or in any case where extreme sensitiveness is an object of importance, the use of iodides and bromides either in connection with a chloride, or for the purpose of entirely superseding it, may be desirable, and they are, we believe, generally preferred. Various proportions of iodide and bromide are used by different operators with the solar camera, with more or less of success. The proportion of iodide is generally about eight or nine to one ounce of water, and the proportion of bromide in conjunction with this quantity of iodide varies in different hands from six to sixteen grains. Probably the proportion used by Mr. Glaisher at Greenwich, in photographing the meteorological and magnetic records, might be found valuable here; they are eight of iodide to twelve of bromide, this proportion being found most sensitive to artificial light, and would probably be found the same for sunlight. The salts of potassium are generally used.

Development printing is best suited to plain paper, but may if desired be used with albumenized paper. The following details given by "Theta" in a former volume, it may be interesting to reproduce here:—

"Take any quantity of the whites of fresh eggs, and to each ounce of this add—

Chloride of ammonium	4 grains.
Citrate of soda	4 „

and water sufficient to dissolve these salts; beat up well, as in other processes, and float the paper upon it for three minutes, hang up to dry; this will keep a long time.

"The citrate of soda is made by neutralising 112 grains of pure citric acid with 133 grains of dry bicarbonate of soda. But in many places it may be procured at the druggist's.

"To excite this paper use 30 grains nitrate of silver, 30 minims pure acetic acid, 1 ounce distilled water; float the paper four minutes at least upon this, and dry in a perfectly dark place. Of course the operator must be particularly careful not to allow the faintest light to fall upon it when it is, or has been, upon the silver bath.

"The exposure is from one minute to ten, the best guide being the appearance of the print. If all, excepting the very lightest parts, is visible, the exposure has been long enough.

"The next stage is the development. The greatest plague in this process lies here. Often have I washed my dishes with *strong* solution of cyanide of potassium, and yet the print has become marbled; whilst, when I have turned up the edges of the print, making it into its own dish, I never had a single stain: the print should not be over developed, as it loses nothing in fixing or toning. A saturated solution of gallic acid is used for this, and as the print is never washed before development it needs the addition of no silver whatever. If the room, however, is *warm* in which the print is developed, a mixture of equal parts saturated solution of gallic acid and water is strong enough.

"To fix, use one part hyposulphite of soda in six parts of water, and allow it to remain in this solution 15 or 20 minutes.

"The prints may be toned with gold before fixing, as in other processes; but, if possible, until they are placed in the hyposulphite, they should not be brought into the light; as, even after well washing when developed, they are very liable to be rendered dirty-looking by the light.

Photographic Tourist.

PHOTOGRAPHIC RAMBLES IN WALES.—No. 2.*

BY J. H. JONES.

In my photographic rambles, I much prefer—when time will allow—to walk, for the pedestrian has a better chance of meeting with those wayside gems, which, when faithfully transcribed by means of our truthful and beautiful art, go so far to render our portfolios attractive. But I may state for the benefit of those who have not the time or inclination to walk, that there are several modes of conveyance to the head of the valley.

The first object of interest to the tourist in ascending the Vale of the Tawe, is the Copper Works, and should the day prove clear, with a south-westerly wind, some excellent pictures may be obtained of them from the turnpike road, the canal side, or the slag banks; the appearance of copper as well as iron works is of course the most impressive at night; and the Swansea Valley at this point forms no bad representation of the infernal regions, for the smell aids the eye; large groups of odd-looking chimneys and ricketty flues emit sulphurous arsenical smoke, or pure flame, a dense canopy overhangs the scene for several miles, rendered more horrible by a peculiar glare. This valley, from Swansea to Morristown, presented, as I wended my way upwards, a scene of busy industry, for here are congregated, within the space of four miles, no less than fifteen works for the manufacture of silver, copper, iron, tin, spelter and chemicals, besides the numerous collieries; the quantity of coal required for these works alone is enormous; and when it is borne in mind that the back freights of the vast fleets that arrive at the port is coal, some idea of the extent of the trade may be entertained.

Stopping occasionally to obtain a view of the largest of the works, here and there, and turning aside to the banks of the river to obtain others, the most prominent of which is the Landore viaduct, after a few hours I found myself at Morristown; there is nothing of interest here, except the Libanus Chapel, but it is so placed that I could not get a picture of it. Thus far the beautiful features of nature are completely defaced by the smoke of the works, and the ranges of unsightly buildings in every direction.

The vale, in its course upwards from Morristown to Hennenadd in Brecknockshire, is continually losing something of its useful, but artificial deformity. Every step I gave from here presented some fresh subject of admiration to my eye; in fact, I may say, that it would be an endless matter for me to describe everything which presented itself. I shall, therefore, only speak of those views, which deserve especial notice, but to those who may follow in my footsteps I can promise a rich fund of the best materials for forming a perfect landscape, on condition that they will turn aside occasionally from the turnpike-road to the canal (which run in many places side by side), which will afford a most agreeable deviation, barring the mud and dirt, of which there is plenty. Indeed, if we would but accustom ourselves to a tenth part of these inconveniences, which we are eager to encounter, swelling, as they do into real difficulties, on a foreign tour, we should entertain higher and more just notions of that variety, grandeur, and richness, displayed by our home scenery; to those who compare it candidly, either with their own observations, or the best accounts of continental landscape.

It was remarked by Wilson—whose authority is not to be disregarded on his own subject—"that a young artist might find, in some part or other of this Island, everything he could attain by going abroad, or, indeed, that he could possibly want to complete his studies, and form his style, excepting what is distinctively characterized as an Italian sky; and it may be much doubted whether English painters are not sometimes induced to show that they have travelled at the expense of propriety." We not unfrequently meet with men of respectable talents and sound judgment in the main, who talk about uniting the brilliancy of Claude with the grandeur and sublimity of Poussin. But surely such a combination of properties is unattainable in practice, and were it not so, it would confound all character, and consequently ought rather to be avoided.

We never see such heterogeneous mixtures in nature, which brings together such things as may harmonise and cooperate with each other; not such as must be eternally at variance. Nor can it be said with truth that there is less beauty in an English than an Italian sky, since each will be found to suit best with the general complexion of its respective scenery. When, therefore, it is considered, that an English student generally intends to exercise his talents on his own country, and for his own countrymen, a foreign education seems not so desirable as it was before we had respectable schools of native growth.

A habit of constantly observing the works of creation as they really exist, rather than as they are set down in treatises or practical specimens of masters, will teach him to vary his style, when he takes his subject from a different climate; but there is no real excellence in sketching a sky, under which vegetation must languish and be dried up; over a landscape whose verdure could only have been preserved in its luxuriance by the frequent distillations of a surcharged atmosphere.

But perhaps some of my readers will say, What has all this to do with photography? and to them I would say that it has much to do with it, and if not with photography it has much to do with photographers; for how many of my photographic readers are there, who would not prefer a tour through France or Italy, or elsewhere, in preference to a tour through the land of their birth? If the public require foreign views, there are surely enough of foreign artists to supply them, therefore, let every photographer look around

* Continued from p. 175.

him, and he will find sufficient work for his camera at less expense than he would at any other place away from his English home; as a proof of this, look at the photographs of English scenery by Fenton, Lake Price, Sedgfield, Bedford, and many others of our justly celebrated photographers; where will you find views to equal or surpass them in point of artistic beauty, or solemn grandeur? There are places, I will not deny, which are more attractive in point of interest connected with historical fact, but *will* these repay the labour and expense of getting them.

I will not digress any further at present, for fear of being tedious, and thereby damp the ardour of my kind readers. So next week I will once more return to the subject in hand.

(*To be continued.*)

Proceedings of Societies.

Manchester Photographic Society.

The monthly meeting was held on Wednesday, the 3rd instant, —Mr. Parry presiding.

Mr. Sidebotham, whose paper was to be discussed, was unavoidably absent.

Mr. Brothers had held at the last meeting that portraits taken with a good lens, with the circular stop, would not show distortion of the character spoken of by Mr. Sidebotham; and he produced four photographs in support of that opinion. The subject was a bust, in which a flowing beard stood out from the pedestal, and would at once show whether the ordinary lens gave rise to a stereoscopic effect not produced by the horizontal stop. The photographs were about one-third the size of the original—the first being taken with the stop with which he usually worked; the second with the full aperture of the lens; the third with Mr. Sidebotham's stop; and the fourth with a similar slit placed vertically. He invited the members to examine these carefully, and he believed they would say with him that no difference could be detected as regards the stereoscopic effect. The beard he had alluded to would prove this; for it would be found to extend to exactly the same point on the pedestal in all the copies. It was possible there might be some minute difference, but the eye could not detect it; and he could not therefore conceive it to be a matter of any practical importance. But he found that, on using Mr. Sidebotham's stop, the time of exposure necessary was three times that which he required when using the ordinary arrangement; and it consequently appeared to him that he should, without gaining anything of importance, lose considerably. Another defect, however, would be observed, and it was in order to show this that the fourth negative was taken with a vertical slit. On examining the pictures it would be observed that in both cases where the elongated stop was employed there was a drawing of the lines in the direction of that elongation, they being blurred horizontally when Mr. Sidebotham's stop was used, and vertically with the vertical stop.

A general opinion prevailed that no perceptible difference, except that pointed out by Mr. Brothers, existed in the pictures produced.

A conversation on the subject followed, in which it was stated that further tests ought to be applied, and several members resolved to experiment before the next meeting, when it was hoped Mr. Sidebotham would be present and the subject be resumed.

Mr. Noton then read some notes on the use of rectangular stops, detailing an experiment he had tried. Taking a stereoscopic camera, he placed a vertical slit-like aperture in front of the right-hand lens, and a horizontal one in front of the left-hand lens. The light was bad, and the circumstances unfavourable for getting a good picture. The subject was a tall chimney with trees, &c., in front. The result was that, with the vertical aperture, the outlines generally were good; with the horizontal aperture, the chimney was deficient in outline and looked slenderer, whilst the trees were remarkably crisp, sharp, and round.

Mr. Brothers said, that precisely the effect he had pointed out, of a drawing of the lines in the direction of the slit, would be perceived—the blurring up the chimney with the vertical stop and across it with the horizontal stop being most marked.

After some further conversation the proceedings terminated.

Photographic Notes and Queries.

The Best Dry Process.

Sir,—Among the multitude of dry processes I am in rather a fix as to which one I should employ. We have Fothergill's, Hill Norris's, Petschler and Mann's, and a thousand others to be found in your four volumes, and to the best of my belief no single hint from reliable authority as to which is really the best for beginners and amateurs who have but little time for experiments. If you would kindly inform me you would, I am sure, confer a great favour on many of your readers I shall certainly be grateful to you.

I have a large gutta-percha bath, and found great inconvenience from the plates catching in the sides while going down. I have put a strip of glass on each side and find that it completely obviates all difficulty; perhaps the hint may be useful to some of your readers who find the gutta-percha bath more convenient in their travels. I may state that for the last two years I have never had my solution out of my bath (which is, as I have said, a gutta-percha unvarnished) except for filtering to remove the small bits of detached collodion, and that it is in quite as good working order now as one that I made and put in a porcelain bath a short time ago. I keep a stock bottle of a 40-grain solution of nitrate to replenish my bath when it gets low, and that is all I do with it. I saw, the other day, an extract from a paper (I think the *Athenæum*) which may be interesting to some of your readers. I do not remember seeing it in the News. It is a very simple way of clearing the printing solution of the red colour. You take a 5- or 6-grain solution of salt and water, put a little into the solution of silver, and agitate violently before any precipitate is formed, when the liquid becomes quite limpid; of course you must add a little at a time until the desired effect is produced, taking care to agitate, to prevent the formation of a precipitate.—I remain, sir, your obedient servant, R. W. K. M.

Highgate, April 15, 1861.

[An enquiry as to the best dry process is one we are continually receiving. It might be asked with equal propriety, "which is the best colour for a ribbon?" or anything else on which diversity of opinion prevails, or which for its answer depends upon circumstances. Every dry process has its advocates, and with all we have seen excellent results. The collodio-albumen process has produced the very best pictures we have seen produced by any dry process, we might add or wet either; but it is not quick, and the preparation of the plates takes time. The Fothergill is more simple and sensitive, but less certain. The resin process is the simplest of all, and very sensitive; but there are difficulties in getting good results. The tannin process is very simple, and gives magnificent negatives, but unless carefully managed there is danger of losing the film; and the process is, moreover, stated to be somewhat slow. In reference to this we may remark that we got a very good negative on a tannin plate the other day, in 18 seconds, with a Dallmeyer's lens with half-inch stop. There is no royal road to success in photography, it is only obtained by patiently working any given process out. Mr. Mudd, the most successful "dry" photographer we know, speaking of the secret of his success in the collodio-albumen process, says, "I have worked at it four years, and never tried any other." See the Report of the South London Experimental Committee in the present number.

The use of a solution forming a chloride, a citrate, or other insoluble salt of silver, for decolorizing the nitrate bath is well known.—Ed.]

Horizontal Stops.

Sir,—Much has been written on the cause and remedy of lenses producing distorted pictures, but in my opinion opticians generally begin their investigations upon wrong premises, they appear to take for granted that they must approach in their lenses the condition of a person with one eye, whereas, everyone knows that the two eyes of an individual produce two distinct impressions of an object, one being to the right or left of the other as the case may be, one superimposed on the other, shew the object, not as it really is from one point of sight, but much broader horizontally, as including part of the side or sides of the object, if it be a small one, at a moderate distance off. Now a large lens of the same diameter as the width apart of the two eyes, gives an image of an object not only broader as the eyes do, but also shews more of the top and bottom, as well as between those extreme parts, on every side which a line drawn from any part of the face of the lens could take in, necessarily therefore, a lens to give a true delineation should have a stop with a horizontal slit for opening, corresponding to the width between the pupils of the eyes and of the breadth of the diameter of the pupils. For general purposes the opening may be a little wider. The rays from the object to the part between the extremities of the slit do not matter, as making a less angle they coincide more nearly than the extreme ends. I wrote the substance of the above on a slip of paper, and intended to revise these few remarks, but being apprehensive from what I have heard that some one else may have forestalled me in writing to you, as I invented the stop five weeks since, and have been working with it four or five weeks in my father's public photographic studio, I write at once. Of course there may be a contemporary invention of the same thing. I am, sir, yours respectfully,

James Vincent Maginn.

Manchester, April 15th, 1861.

[We presume our correspondent, although dating from Manchester, is not a member of the Manchester Society. At the March meeting of that society Mr. Sidebotham read a paper on this subject. Mr. Maginn's experiments appear to have been contemporaneous with Mr. Sidebotham's. If the date of such an idea be of any interest, we may state that we tried it some five or six years ago, covering the front of a portrait lens with a piece of brown paper with a horizontal slip in the centre. We arrived then at a similar conclusion to that which Mr. Brothers has come to—we discovered no practical difference, except loss of light.—Ed.]

Correspondence.

FOREIGN SCIENCE.

[From our special correspondent.]

Paris, 17*th April*, 1861.

There is every prospect of a brilliant Exhibition of photographs opening here on the 1st of May. Most of our most eminent photographers, animated with a feeling of national pride, no less than of personal ambition, have exerted themselves to the utmost to render full justice to the present capabilities and resources of the photographic art. All the foreign contributions that will be received, have, of course, now arrived; but at present I am unable to state in what quantity, although there is reason to suppose that the English quota is less than could be wished. Probably, before my next communication is penned, the catalogue of the Exhibition will be printed, and then all doubts and surmises will be set at rest.

Mr. Aichs, of Brussells, has introduced a new metallic alloy, which is much cheaper than red copper, and even lower in price than brass, while it can advantageously replace those metals in naval constructions, and other branches of industry. It has more tenacity than copper or brass, and is less subject to oxidation. It possesses the great advantage of working as well cold as when heated; it may be forged without losing its cohesion; it melts readily, and can afterwards be submitted to the operations of hammering, rolling, and punching. In a state of homogeneous fusion, this alloy consists of 60 parts copper, 38·2 of zinc, and 1·8 of iron.

The conversion of iron into steel has taken another step towards a satisfactory theory of cementation, through the labours and intelligent experiments of Captain Caron. The result of his last researches may be summed up as follows:—1st. That in industrial cementation, acieration is always produced by means of a cyanide, which is formed naturally in the cementation boxes, by the reciprocal action of carbon, nitrogen, and the alkalies present. This is the reason why the presence of nitrogen is indispensable. 2nd. That, nevertheless, under certain circumstances, it is possible to cement without the presence of nitrogen; which proves, *en passant*, that steel is not, as some chemists have attempted to prove, a nitro-carbide of iron. 3rd. That to cement it is necessary and sufficient that the agent of cementation be a volatile or gaseous compound, but indecomposable at the temperature employed; in this manner the carbon is brought to a state of combination in the very pores of the iron where this metal appropriates it in its nascent state. 4th. That native carbonate of baryta, or carbonate of strontium, mixed with carbon is susceptible of becoming one of the most useful and economical agents of cementation, on account of its unalterability and its power. The question of effectual and economical cementation of iron would appear now to have attained a satisfactory solution. The above mixture, once formed, may be employed indefinitely, it will only require the addition of a small quantity of carbon occasionally, to supply the loss of such portions as may be accidentally consumed. The barium, after yielding up its carbon to the iron, becomes regenerated by the oxide of carbon, always present at the same time with nitrogen, in the cementation boxes.

It is considered probable by many chemists that new investigations into the constitution of certain bodies now regarded as simple or elementary will result in showing that they are only compounds. The number at present admitted to be simple does not at all harmonise with the simplicity of means prevalent in the operations of nature. Many probabilities concur to show that certain so-called simple bodies are either condensations or combinations formed by nature under great pressure, sometimes accompanied with high temperature, and by elements upon the simple nature of which there can be no question. It remains to be seen if science cannot experimentally attack, with hope of success, the problem of their composition. We already possess powerful apparatus of compression, we know how to obtain vapours under very great pressure, and compel them either by heat or by chemical process to produce it in relatively small spaces. The depths of the ocean furnish us with facilities for submitting bodies to enormous pressure; and, by electricity or by mixtures, we can excite chemical reactions at great depths below the earth's surface. Thus, it would appear, we have all the recources for attempting the synthesis of certain simple bodies under conditions similar to those which apparently were employed in nature in the formation of most of them. In every group of simple bodies, evidently analagous, every intermediate body possesses a union of properties, presents a type which the body immediately superior and the body immediately inferior can create by contracting one with the other, in suitable proportions, an undecomposable combination. A bromine, for example, is a sort of chloride of iodine; a phosphorus, is a sort of nitride of arsenic; an arsenic, a sort of phosphide of antimony; a selenium, a sort of sulphide of tellurium, and so on. It is not, however, necessary that these bodies should be of the same group to produce such or even more remarkable coincidences. The properties of carbide of nitrogen, C_2N, or cyanogen, so analogous to those of chlorine, leads to the supposition that chlorine may be a nitride, either of carbon or some analogous body, but a nitride undecomposable by any means at present employed. Speaking according to the laws of fusibility, bromine and iodine may have an analogous composition, only either, will be in lesser and lesser proportions, or the carbonoïd radical will be heavier and heavier. At the period when the temperature of the earth was at the melting point for the whole mass, the waters now spread so profusely over its surface formed with a quantity of matters now solid or liquid an atmosphere the pressure of which must have been enormous. When vapours are formed abundantly at great depths below the surface of the earth in spaces completely closed, the pressure they exercise, other things remaining equal, must also be enormous. Physics show this to be the case, and the prodigious force put into action during earthquakes and volcanic eruptions appear to afford an example. These enormous pressures, generally neglected in our chemical reactions, must play a very important part, which appears to be very useful in the question now under consideration. These remarks, however imperfect or incomplete they may appear, will serve to indicate the direction chemical research should take in the investigation of the elementary nature of so-called simple bodies.

Talk in the Studio.

Light in Dark Places.—Our readers are doubtless aware that, until recently, photography was banned in the greater part of Italy as an unhallowed thing. A new era in that as well as many other things is inaugurated under the reign of Victor Emmanuel, King of Italy, and photography is received under especial favour of government. M. Dallmeyer has just received a large order from the new Italian government for lenses, amongst which are two of his triple achromatic combinations, one of 40 inches focus, to take pictures 30 in. by 24 in., and another to take pictures 15 in. by 12 in., and also a portrait combination for pictures 12 in. by 10 in. It is highly gratifying to record the recognition these new lenses are receiving on the continent.

Large Lenses.—The photographic department at South Kensington Museum have just ordered one of the triple achromatic lenses to produce negatives three feet square; they have one in use already covering 25 in. by 21 in.

Lecture on Photography.—Lectures on photography seem for some years to have almost entirely ceased. We are glad to find some hope of their revival in the hands of a gentleman so accomplished as Mr. Vernon Heath, who lectured at Aylesbury, in the Mechanics' Institute, on the 27th ult., the Rev. J. B. Reade, the first photographer in this country, presided. The lecture was illustrated by some interesting experiments. By means of the brilliant light of phosphorus burnt in a jar of oxygen, the word "light" was printed on sensitive paper, and a negative of a bust taken by the aid of the same light.

Stereoscopic Exchange Club.—We regret to state that we have received several letters complaining of the inferiority of many of the prints forwarded as exchanges by some members of the Stereo Exchange Club. One correspondent states that, out of twelve dozen he has received, he cannot select two dozen good pictures; and that in many cases the worthlessness of those received arises out of downright carelessness, as not less than fifteen have been mounted in the wrong position, the left picture on the right side. He adds the significant fact, that most of the bad pictures are by some dry process; whilst the balance of good results are by the wet process. Another correspondendent sends us up specimens of what he has received, some of which are simply disgraceful, and are the worst we have ever seen. We were fully prepared to expect that some poor prints would be sent out in this way, and that possibly in good faith, as some persons, beginners especially, are wonderfully blind to the defects of their own pictures; but some of these are so bad as to admit of no excuse. We really hope that to prevent the entire cessation of this pleasant interchange, members will act with consideration and fairness, and send out nothing in any degree inferior to those which they hope to receive. If, however, the suggestion be acted on which we made sometime ago, we think much disappointment might be prevented. If members in commencing to exchange with any new member begin with one or two copies, and only proceed further on finding that the exchange is likely to be satisfactory, no great harm can at any time be done. This, we think, would prevent disappointment more effectually than any classification which we could make, and would be a much less invidious proceeding.

Copyright in Works of Fine Art.—The Bill for amending the law relating to this subject, which was to have been brought into the House of Commons by the Solicitor-General at the commencement of the Session, was not brought forward until Monday evening last, when the Attorney-General moved for leave to introduce it. He hoped the House would take for granted the necessity for such a Bill. The artists of all nations in the world were invited to bring their works to this country in 1862. We had entered into treaties with other countries and established an international copyright, yet there was not in this country any law that gave protection to copyright in works of the mind, which above all others were entitled to such protection. Leave was given to bring in the Bill, which was then read for the first time.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

To Correspondents.

J. L.—Bromide of cadmium is moderately soluble in alcohol, much more so than most of the bromides. Bromide of potassium is very sparingly soluble in alcohol: it is difficult to get more than one-fourth of a grain in each ounce of collodion. The best method of adding a bromide is to dissolve it in the iodizing solution before mixing with the collodion. Your stereograph is scarcely up to the mark. It is very much under-exposed. We shall not publish a list for a few weeks, and shall be glad to know that you have got some other negatives in the meantime. The addition of a small portion of bromide to your collodion and iron development will cure the hardness which characterizes your specimen. We must impress upon you and some other correspondents that it is utterly inexcusable to send letters without paying the postage. We had to pay four pence for the privilege of criticizing an imperfect picture.

X. Y. Z. asks us what are the defects of Powell's dry process, as he presumes it has turned out a failure, notwithstanding that he has obtained and seen some good negatives by it. We have not tried it and cannot speak from personal experience; but we believe that similar difficulties were found in the use of glycerrhizine, to those which some have found in the use of tannin, namely the tendency of the film to leave the plate. Whether these were insuperable difficulties or not we cannot tell. Mr. Ackland has, we believe, worked it successfully, and, we fancy, does so occasionally still.

C. S. Trawels.—You will find full details of the manipulations in the tannin process in our numbers for the 15th and 22nd of March.

J. Smith.—The mottled red spots in your print arise from some imperfection in the paper; try another sample. We have produced excellent tones by various alkline gold formulæ. Here is a very simple one which we gave to a pupil the other day, who brought us a day or two after as his first attempt, some as finely-toned prints as we should wish to see: chloride of gold, 1 grain; carbonate of soda, 5 grains; water, 8 ounces. 2. Hypo will keep perfectly well in solution: by new hypo is meant a solution which has not been used, but not necessarily newly prepared. 3. Your silver bath should not be less than 60 grains to the ounce. 4. Take your negatives direct, by one process if you can do so successfully; only use intensifying processes to gain some advantage, not otherwise attainable. See a recent editorial article on intensifying processes. Your lens does not cover sufficiently for a standing figure.

P. L. L.—The shape which prints shall be cut previous to mounting is much a matter of taste, and must be governed largely by the character of the composition. In many cases there is nothing more satisfactory than a simple rectangular shape, such as is given nine times out of ten to drawings and paintings. Sometimes it happens, however, that by the use of the oval circular or dome shape something is got rid of, the absence of which vastly improves the picture; and sometimes the whole effect of the lines in the picture is altered and improved by the shape to which the print is cut. As we have said, it is a matter of taste; but do not imagine from this that we mean that it is purely arbitrary; good taste in such matters arises either from a carefully acquired knowledge of the laws of composition, or from an instinctive perception of them with which some persons are gifted. We have seen in some of Mr. Mudd's pictures, the immense value they acquired from taste and judgment in this respect. At times, where a series of straight vertical lines have been the only defect in a beautiful landscape, that defect has been entirely got rid of by cutting the picture a circular shape.

Proto.—A good rule in making an iron developer, is to use as many minims of glacial acetic acid as there are grains of protosulphate of iron in the solution. No rule can be given for the use of alcohol, as that depends on other conditions: as little as will make the developing solution flow freely and evenly over the plate. Methylated alcohol answers perfectly well in the developing solution; we have used it for years.

Tripod.—As a general rule the camera stand should be of such a height as to allow the lens to be about the same height as the eyes; say about five feet six inches from the ground.

W. H. B.—If the varnish only has cracked, the evil may be remedied by dissolving off the film of varnish by a proper solvent, which only can be determined by the kind of varnish; but if the film of collodion also be cracked, there is no remedy.

W. W.—A very small quantity of dilute nitric acid will prevent the streaks being formed on the film. See also that there is no scum on the top of the solution, as that sometimes will cause streaks; also let the film set well.

Brom. Cad.—Where the pyroxyline has been made at a low temperature, or with very strong acids, cadmium salts have a tendency to gelatinize the collodion. Time will largely remove this defect, and the addition of a little more ether to the collodion will improve it when that gelatinous tendency is shown. The film is generally somewhat paler when the collodion contains a bromide; we generally add extra iodide when we use a bromide. All the bromides are less soluble than the iodides, but bromide of cadmium is easily soluble in alcohol as compared with most other bromides. On adding the bromide of cadmium to a solution of iodide of potassium, the milky turbidity and white precipitate are caused by the formation of bromide of potassium which is very sparingly soluble in alcohol, and is consequently thrown down. Not more than a quarter of a grain of a bromide to each ounce of collodion can be conveniently used in conjunction with a potassium iodizer; but if you add it freely the cadmium base which left the bromide would unite with the iodide, leaving the potassium, and thus you may have a large quantity of cadmium in your collodion, and this with a pyroxyline made at a low temperature, would produce the glutinosity of which you complain.

G. G.—The camera should be polished after it is completed, but before, of course, the lens and flange are in their places. You can buy French polish ready made at the oil shops; or make it by dissolving equal parts of shellac and sandarach in methylated spirits; the proportions we do not remember at this moment, but it must be of about the consistency of cream. Press of other matter more strictly photographic, has prevented the appearance of mechanical articles. It is still in contemplation to reprint and enlarge the articles in question.

M. L.—We will insert your name. The Water Works are very good indeed. The other a little under-exposed. Don't be afraid of exposure with dry plates. We are obliged by your good opinion.

A Lady Photographer and some other correspondents next week.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 138.—*April* 26, 1861.

A NEW PROCESS.

Last week we found it necessary to caution our experimental readers against building hope upon a process originally announced by Mr. Bellini in our columns, and revived when we had forgotten it, in the columns of a French contemporary. We have this week to announce to our readers the discovery of a process, scarcely less startling in its claims than the one to which we have referred, and in one of its features, at least, analagous to it.

Unlike Mr. Bellini's process, this comes before us with credentials, which entitle it to attention; and we can speak personally, so far as very limited time for experiments permits, of its success.

The chief aim of the process is to dispense with the use of a bath of nitrate of silver, or of any other substance, in the production of negatives on glass. A preparation is poured upon the plate, whereby an even, homogenous film is produced, which is sensitive to light, without further treatment of any kind. The exposure and development are then the same as in the ordinary process, either the salts of iron, or pyrogallic acid being used as a developer.

The conception of the idea is due to Captain Dixon, whose photographs of Indian temples and other subjects, many of our readers may remember in the exhibitions of the Photographic Society, and of the Architectural Photographic Association. The details have been worked out, so far as they have gone, by our contributor, Mr. Samuel Fry, in conjunction with Captain Dixon. As we conceive it to be very possible that the germ of a very considerable modification or revolution in the ordinary negative process may spring from this discovery, we may state briefly, in detail, how the matter stands. Mr. Fry called upon us one evening this week and showed us some stereoscopic negatives, and asked for our opinion of their character. They were red vigorous negatives, some of which were much over-exposed. One marked as having had three seconds and a half was slightly under-exposed; and another marked as having been exposed seven seconds was nearly right, but would have done with a second or two less. A portrait combination, with small central stop, had been used. We were then informed that these negatives had been produced without the aid of any bath of nitrate of silver; the sensitive film being produced at one operation by means of a preparation poured on the plate.

The following morning we attended at the laboratory at King's College for the purpose of testing, in conjunction with Mr. Sutton, Mr. Rouch, Mr. Fry, and Captain Dixon, the results of the new preparation. It unfortunately happened that there was a foggy bad light, which rendered photographic experiments comparatively useless. Some pictures were obtained, but they were not perfect.

We have ourselves since taken three or four pictures by means of the preparation. In our hands, so far, it has proved a trifle less sensitive than wet collodion, and there is also a little lack of vigour. We have, just before writing these lines, taken a negative, with an exposure of about forty seconds, without sun, and dull light, a Dallmeyer's portrait lens of about six inches focus, and three-eighths stop. The negative is perfectly full of detail, but a little wanting in vigour.

Much probably remains to be done in settling the precise formula for giving the best results, both as regards sensitiveness and vigour; but we think that it is obvious that a compound, containing in itself all the necessary sensitive salts, in proper proportion and due relation, must possess advantages altogether unattainable by the use of nitrate bath where an uncertain amount of iodide of silver is formed, plus an indefinite quantity of free nitrate, plus an indefinite amount of other unknown matter.

Steps are in progress for patenting the preparation which, by the time these lines are in the hands of our readers, will be completed. The matter will then be put to the practical test, which must decide its worth.

Since the above remarks were written, we have received a letter from Mr. Bellini, which, as it bears upon the question, we may refer to here. Mr. Bellini thinks we have done him injustice in the caution we felt it necessary to give experimentalists, in reference to his alleged discovery. He asks us to suspend judgment until next week, when he will reply, at length, to our remarks. The best reply Mr. Bellini can make is to give actual demonstration. If he has received any injustice, he has only himself to blame. We gave him a fair field, and took some trouble to allow him every opportunity of substantiating his statements. From whatever cause, he did not do so: and the last personal statement he made to us was, that as he had not succeeded in his operations in our presence, he would send us, in a few days, a bottle of his preparation for our own experiment. Six months have now elapsed, and it has not arrived.

MODIFICATION OF THE FOTHERGILL PROCESS.

We call the attention of our readers interested in dry photography to a modification of the Fothergill process, suggested by Mr. Hannaford, by which considerable uniformity of result and immunity from stains is obtained. Instead of adopting the plan of a partial washing, whereby an uncertain amount of nitrate of silver is left in the film, or the use of a second weak silver bath, giving a definite amount of nitrate, but which involves extra trouble, Mr. Hannaford washes the excited film thoroughly in an unlimited amount of water. This being done, there is no silver left to form the albuminate of silver, or other compound of salt, when the preservative is applied. Mr. Hannaford, however, forms that salt, whatever it may be, in his preservative solution, by the addition of a given amount of nitrate of silver to it.

It must be evident that one essential cause of stains and irregular deposit is here eliminated. It is clear that on the application of a preservative solution, forming a compound salt, with the free silver already in the film, a very different result is produced at the first point of contact, to that which occurs when the solution has spread itself to the furthest part of a large plate. In Mr. Hannaford's modification, however, no new compound is formed on or in the plate, but, being applied in one homogeneous solution, an even and harmonious deposit of silver in development is the result. The details are given in the report of the Experimental Committee of the South London Society, published in our last, and in the present number.

It is only just, here to remark, that whilst to Mr. Hannaford is due the careful working out of this plan, the idea was suggested in our columns nearly three months ago by Mr. Bartholomew, of Fareham,* and we have before us an excellent negative taken by that gentleman on a plate prepared by that method. At the time we made a similar suggestion to that made by Mr. Borchert at the South

* See p. 53 of present volume.

London meeting the other evening, namely, that the keeping qualities of the plates would probably be injured. That point yet remains for time to prove. It is due to Mr. Hannaford to say that we believe that the idea was an original one so far as he personally was concerned.

A slight alteration will also be found in Mr. Davis's method of working the collodio-albumen process, in the above-mentioned report, to which we call attention.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Another chloride which is of great use to photographers for several purposes is the *chloride of calcium*. This may readily be obtained in commerce; nevertheless as some of our readers may be so situated as to be unable to procure this salt, whilst they may perhaps have the materials from which to make it, we will follow the same plan that has been adopted with the salts which have come under our notice in previous chapters. It is prepared, on the large scale, in many ways, and is also met with as a by-product in the preparation of caustic and carbonate of ammonia, by the re-action of lime on chloride of ammonium. Amateurs will, however, find it preferable to prepare this salt in a manner which is seldom adopted by manufacturers, from its expense, as the great solubility of chloride of calcium in water will prevent the method of purification by crystallisation, so frequently recommended in these articles, from being employed. Pick out some of the whitest and purest looking lumps of marble that can be obtained, and place them in a moderate-sized evaporating basin. Cover them with a funnel placed upside down over them, with the stem pointing upwards and uncovered. Now pour round the hollow edge of the funnel some pure white hydrochloric acid. This will run under it amongst the marble and will produce a lively effervescence, whilst the funnel will form a covering to prevent the splashes of liquid sent up by the bursting of each bubble of carbonic acid, from falling over to the outside of the dish. As the action of the acid seems to abate, add more, until the marble is nearly all dissolved. Then place it over a source of heat and warm to get rid of the carbonic acid dissolved in the liquid, and afterwards filter it from the impurities which may remain undissolved. Place the clear liquid in an evaporating dish, and evaporate it over the water bath until it is highly concentrated, when cover it up and allow it to cool. Crystals of hydrated chloride of calcium will be deposited on cooling, which must be strained off, allowed to drain in a funnel, quickly dried in blotting paper, and preserved in a well stoppered bottle. These crystals consist of anhydrous chloride of calcium combined with six atoms of water. They are still highly deliquescent, melt below 100° C in their water of crystallisation, and at 200° C fuse and part with four atoms of water, leaving a white porous mass. As this latter compound will be frequently required in the laboratory, it will be advisable to prepare some of it before hand from the crystallised salt, and preserve it in another well stoppered bottle. If this dried salt is heated above the melting point, but still below ignition, the compound swells up strongly and gives off the whole of its water. The anhydrous salt dissolves in water with evolution of heat, but if the crystallised salt be taken, cold is produced. It is, as before stated, extremely deliquescent, 100 parts in powder, absorbing from a damp atmosphere, in 96 days, 124 parts of water. The crystallised salt dissolves in half its weight of ice cold water, in one fourth of its weight at 16° C, and in every proportion of hot water. It is readily soluble in alcohol, both in the dry and hydrated state.

The uses of chloride of calcium to the photographer and scientific man are numerous and important. Owing to its powerful affinity for water, the dry salt forms one of the best materials known for the removal of moisture from liquids as well as from the atmosphere or gases. Thus it has been much employed for separating the water from alcohol and ether, which is easily effected by allowing them to digest together and then distilling. It is also sometimes used for drying the atmosphere of boxes which are destined for the preservation of sensitive paper and plates. For this purpose, however, it is almost too energetic, as it has been found that no advantage, but rather the reverse, is gained by having the air absolutely anhydrous. Its ready solubility in alcohol renders it likewise in great favour amongst some makers of collodion, as it offers an easy means of introducing in this article a certain quantity of chlorine. The deliquescent nature of the salt, and the great mess it makes if any of it is spilled about on the table or floor, are objections in the way of its general use. The crystals reduced to powder, are largely employed in the production of artificial cold, by being mixed with pounded ice or snow; a temperature sufficient to freeze mercury being readily obtained.

Another compound containing calcium and chlorine may conveniently be noticed here—the substance known as *chloride of lime*. This important substance is prepared on a large scale by saturating well slaked lime with chlorine gas, rise of temperature being avoided. The chlorine is prepared from peroxide of manganese, common salt, and sulphuric acid, heated together in a cast iron or leaden vessel, and the evolved chlorine passed into large chambers containing the lime. Thus prepared, chloride of lime is a white powder usually moist and smelling slightly of hypochlorous acid. Its composition is not known with absolute certainty, but it most probably consists of equal equivalents of chloride of calcium ($Ca\ Cl$), and hypochlorite of lime ($CaO.\ ClO$). If properly prepared it contains nearly the theoretical quantity of chlorine to form the above, but never the exact amount, because either more or less of the lime remains uncombined. Chloride of lime must be preserved in well closed vessels kept cool and away from the light; exposed to the air it soon attracts moisture and finally deliquesces, slowly evolving oxygen gas, and forming a liquid which no longer bleaches. In solution chloride of lime forms a transparent and colourless liquid, known under the name of bleaching liquid, having a slight odour of hypochlorous acid, and an astringent taste; when boiled, it loses its bleaching power, and even in close vessels at ordinary temperatures the liquid slowly evolves oxygen gas, especially if exposed to light. All acids, even carbonic, convert it into a lime salt and free chlorine, if added in sufficient quantity; they also give rise to the evolution of hypochlorous acid. Bleaching liquid destroys organic colours, and the odour of decomposing organic matter, but only in the presence of an acid which sets the chlorine free. The value of chloride of lime for removing bad smells arising from putrifying organic matter is well known. The photographer who works with albumen and other animal or vegetable matters, will find it advisable to clean with this substance the floor, &c., upon which such organic liquids fall, and also to throw some frequently down the sink, as nothing tends to the failure of photographic operations so much as the presence of disagreeable odours in the room. It must, however, be borne in mind that the vapour from chloride of lime is injurious to sensitiveness, and it should therefore be guarded against.

Another chloride which is sometimes used in photography is the *chloride of magnesium*. This may readily be formed by dissolving magnesia alba in dilute hydrochloric acid, and evaporating the solution. It crystallizes with difficulty in needles and prisms, and has a sharp bitter taste. It is deliquescent in the air, dissolves in less than its own weight of cold water, in five parts of alcohol, sp. gr. 90°, and in two parts of alcohol of sp. gr. ·817. It will be pure if prepared with pure materials, but its purification, if impure, would be a matter of considerable difficulty to one unaccustomed to the details of chemical manipulation, and should not, therefore, be attempted by the amateur. Pure magnesia and hydrochloric acid are readily to be got free from impurity.

Chloride of cadmium is prepared by saturating dilute hydrochloric acid with either metallic cadmium or its oxide, then filtering and evaporating to the crystallizing point. It forms transparent rectangular prisms, which deliquesce readily when heated, and are readily soluble in water. They may be purified by straining from the mother liquor, in which they have crystallized, and then dissolving in a fresh quantity of water and recrystallizing. The anhydrous salt may be prepared by heating the crystals to the fusing point; it then presents the appearance of a transparent mass, having a pearly, metallic lustre, and laminated texture. It is somewhat soluble in alcohol, although not so much so as the iodide or bromide of cadmium, or some of the chlorides we have just treated of.

Chloride of silver is so well known to the photographer that a lengthened account of it may appear unnecessary, nevertheless, an account of its formation and principal properties will properly follow the descriptions of the other chlorides. Chloride of silver is formed by precipitating the nitrate with common salt or hydrochloric acid, and washing the curdy, white precipitate. It fuses at a temperature below redness, forming an orange yellow transparent liquid, and volatilizes unchanged at a higher temperature. It is also formed by the action of hydrochloric acid, or of solutions of chlorides, upon all salts of oxide of silver, even those which are insoluble in water.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Bright or Brilliant.—Terms sometimes used to express a picture's luminous character; but the quality so described is really the effect of a combination of others, resulting from the judicious arrangement of light and shade in securing a focus of both the one and the other in such positions as may by contrast improve both; giving the light increased brilliancy, and the shade greater apparent depth. I have already urged an extremely careful use of both white and black as the extremes of a photograph's scale of tones, and shown that a waste of the power so given is destructive of a *bright* or *brilliant* effect. Nothing is more productive of brilliancy than a breadth of chiaroscuro, which almost necessitates the preservation of a focus of light, and one of dark. Even and uniform tones produce a monotonous appearance which is the reverse of "bright" or "brilliant," as we must all know; and too much white, or too much black in a picture, will produce the same want of luminous effect by destroying the pictorial foci. The glittering effects of polished metal given by the sharp and direct contrast of the focus of light, and the focus of dark, may serve to illustrate my meaning. In representing this we have only the ordinary black and white, but the first will appear of greater depth, and the second more bright, than the same pigments in other positions, simply because they are brought more directly into contrast. Of course this is an extreme case, but it illustrates very pointedly the value of white and black as the foci of a monochrome picture's tones. The skilful application of this rule will bring all a photographer's art-knowledge into play, and very probably necessitate no little head-work; but the result will most certainly fully repay him for his pains, and, as I have so repeatedly said, tend to raise his art in the estimation of a public powerfully influenced against photography as anything but a mere mechanical process to be classified with—well, I need say no more, you have doubtless seen where our sage friends in authority will place it in the next great exhibition. Dear, dear me; how blind are those who will not see!

Brasses.—Metal plates upon which were represented armorial bearings, portraits of the deceased's figure and costume, or religious emblems, with appropriate inscriptions. As chronicles of costume, evidence of ancestry, and historical relics, these possess very great interest. Photography has been applied to the re-production of these plates by Mr. John Louch. This gentleman's method of proceeding, we extract from an article which appeared some time since in our contemporary, *The British Journal*:—"From an ordinary rubbing, a negative is formed in the pressure frame by exposure to light, and this is fixed and waxed in the ordinary manner. Sensitized chloride papers are then exposed under the negative until the parts which are bright in the original 'brass' are thoroughly *bronzed*, and the parts corresponding to the *blacks* of the negative (that is the *lights* in the positive print) have become black from very extended over-exposure. A dense and well defined negative is that best to operate with; and the positive paper should be both rich in chloride, and also in free nitrate of silver, but not highly albumenized. The printing should be slowly performed in diffused light. The proof then requires fixing and toning with gold, the bath being tolerably rich in the latter material: the effect produced being to *deposit the gold in a metallic form* upon the bronzed portions of the proof, while the other parts acquire a rich black colour, so that the finished specimen bears a striking resemblance to the original 'brass.'"

Buhl-work.—A kind of ornamental furniture frequently introduced into pictures, from its fashionable and picturesque character, and from being generally so designed as to supply a great variety of elegant and contrasting lines, which materially aid composition.

Cabinet-pictures.—Applied to small highly-finished works, which, in consequence of their size, are hung near the eye, and inspected closely.

Caricature.—Photography has been applied to this branch of art, with no small success, by Rejlander; and very ludicrous effects have been got by photographing from distorting mirrors, &c.

Character.—Every individual object in nature having its own peculiar character, it is important that such should not only be preserved, but that it should also be conspicuously visible; for instance, qualities which are characteristic of nearness should be found in the foreground, and those which indicate remoteness should have their place in the distance, instead of aiming by choice of collodion and development, combined with the mismanagement of a lens, to bring the distance forward with clear, *sharp* details, and throw back the foreground by a *comparative* loss of vigour and definition (all that the former gains being invariably at the expense of the latter.) The character of sunlight is frequently destroyed by an over-intense negative, which tends rather to convert the thoroughly diffused brilliancy of solar illumination into the patchy, ghastly lights, and intense shadows of moonlight. Again the peculiar character of flesh, with its glossy and downy surface, its semi-transparency, and its just proportions of yielding softness and firmness, demand for its proper representation all the photographer's judgment and skill: and how seldom do we see this exquisite surface truthfully represented in the photograph. T. R. Williams' pictures are the best I know for giving flesh its own true and peculiarly beautiful character, but he stands almost alone. It is the same in painting, *flesh*-painters are remarkably scarce. It would not take you very long to name all the artists whose painted flesh deserves the name. Before quitting this subject, however, I will just add a few hints relative to a proper representation of the character of water, an element which is almost as seldom represented truthfully in the photograph as proper atmospherical effects. The ripple, or "jaugle,"* of water, may convey the idea of opacity, if it be so photographed as to present only the shadowed side of the ridges to the spectators. But if such a point of view is selected as secures, to some extent, both the lighted and shadowed portions, the result will certainly be more characteristic. This will be mainly influenced by the height of your camera, or rather its tripod stand. Rippled water is best photographed in light, while calm, clear water, is best taken in shadow; the former, when in shadow, losing the very expressive and valuable character

* A nautical term.

of transparency and depth; and the latter, when too strongly illuminated, producing solarization in your exposed plate. Upon any highly polished, smooth, transparent surface, it is very difficult to obtain strong contrasts of light and shade: for this reason, an extensive sheet of smooth water requires very careful management to secure pictorial effect, although such a surface, reflecting light less powerfully than rippled water, is frequently more successfully photographed. The camera's point of elevation is a very important subject of consideration when photographing the surface of water. Reflections in water are most valuable aids in securing its true character, and it may therefore be well for the photographic operator to remember that, on rippled water, such reflections may be visible or not, according to the position occupied by the camera; and also that, by the same means, reflections may be lengthened or shortened. Reflections on rippled water fall only on one side of the ridges, consequently, if your camera gets its view from the opposite side, they will be lost. I have frequently seen water represented as a glaring patch of white paper, when the operator, by simply raising his instrument, might have brought the reflection of a mass of green foliage down into his water, by which the surface would have been materially altered, so far as its photographic results were concerned. Reflections so vary from different points of view, that the artistic photographer should select such when taking this very difficult element with the most earnest care and careful consideration. The nearer the level of the camera is to the surface of the water, the less visible will all the reflections become. As a rule, the ray which pertains to reflection, and that of incidence, according to the laws of perspective, form equal angles. This may be studied from a looking-glass with advantage. I am loath to quit this subject, because so much remains to be said; but I have other duties which are just now crowding every hour of my time, and so perforce must conclude, merely urging upon my readers the importance of considering the characteristics of the things they represent, as well and as thoroughly as the means by which they are represented. There is a great difference between *seeing* and *observing*, you know; and the eye must be educated through the mind to understand imitative art, just as the ear is educated through the mind before it understands musical art. If I do not recognise the thing I seek when it is before me, I have small chance of being rewarded for the search.

ENLARGING SMALL PHOTOGRAPHS.

A Simple Means of producing Enlarged Copies of Pistolgrams, or other Small Photographs.

BY T. SKAIFE.*

A microscopic photograph, whether under the name of pistolgram or otherwise, although generally appreciated for its *multum in parvo* properties, by eyes that luxuriate in small print, yet as "change comes o'er the spirit of the dream," so it is with the idol of affection, whose image secreted in a little gold locket, is there exclusively worshipped by one devotee.

But when the beloved one merges into *Paterfamilias*, so does his image require an amplification of proportion, not only to meet the necessities of patriarchal eyes, but to be in keeping with the patriarchal gallery. Here, our art science has stopped short, to the satisfaction of sundry artist painters no doubt, but not equally so to those who would see in the life-sized family portrait that truthfulness perceived in the miniature photograph.

To meet this want, photographers are now taxing their ingenuity, and using enlarging cameras with more or less success.

Chiefest, perhaps, among the enlarging species is Woodward's solar camera, but which so well adapted for sunny Egypt, or Brighton during the "dog-days," stands small chance of being appreciated in the neighbourhood of London smoke, while the sun is walking south of the Equinox.

To a modification of the electric light, the hopes of the cloud-capped and fogged photographers now turned. But not to waste time in anticipation of the epoch, when the sun is to be outshone at noon-day, I have trimmed me a chamber lamp, which, with its complement of wick and oil, costs sixpence. This on being lit, and placed within the focus of a glass reflector, can have the image of its flame reflected upon the surface of a pistolgram. Now supposing an enlarged reproduction is required from the small photograph, I replace it in the back of the pistolgraph, which I pose opposite the reflector, at a distance from the latter of about double its radius, and place the lamp midway, or nearly so, between the two, moving the lamp backward or forward until the pistolgram becomes brilliantly illumined. Now if a white screen be placed in front of the pistolgraph (from which the shutters have been removed) say at the distance of three feet, an enlarged picture will appear projected thereon *à la* magic lantern. Beneath the screen upon which the magic photograph is projected I place a second table *vis à vis*, the first upon which stands the pistolgraph, lamp, and reflector, a sufficient space being left between the two tables to admit of the operator and his chair.

Upon the second table I place a drawing-board, fixed perpendicularly in a foot, which, when viewed in profile, has the form of a ⊥ square. In this instance my drawing-board, you will perceive, is a stout mahogany picture-frame, across the back of which two pieces of wood are screwed, so as to form a groove into which the frame is pressed. On the plate-glass in the frame, I fix a sheet of drawing or common cartridge paper, by the two upper corners, with a little gum. This done, I next decide on the size of the required enlargement, sliding the drawing-frame nearer or farther from the pistolgraph, and obtaining a proper focus that way, or by turning in or out the screw of the lens.

I then take a small sable pencil dipped in a little neutral water tint, and pass it over all the light parts of the picture, repeating the process until the illumined parts have attained the shaded density of the shadows. Which done, on bringing a light to the front of the lens, an imitation photograph will be found to be the result. And although this imitation, if hastily done, will be found wanting in some of the minor details of the original, the deficiency will be more than compensated by the better adaptation of the imitation than the genuine photograph to receive colour thereon when applied by the skilful touch of an accomplished artist. For the material upon which most artists prefer to paint, whether in oil or water colour, is not generally that best adapted for a photograph, and *vice versâ*. Nor does experience prove that a painting, whether done in water or oil on a photographic base is as durable as one otherwise painted.

Formerly the Messrs. Dickenson, of Bond Street, whose pictures from photographs have attained to such high celebrity, painted, upon the photograph; but in consequence of the numerous complaints made of the fading of pictures so painted, I was informed some months ago by one of the firm, that they had abandoned that system, and now employed competent artists to copy all their best photographic portraits by hand when intended to be finished in colour from the life. The experience of the Messrs. Dickenson, coupled with that of others, added to the no small trouble entailed in obtaining an enlarged negative from a micrograph, has induced me to adopt the plan just described, which, where only one or two enlarged reproductions are required for artistic purposes, answers excellently. A great saving of time being effected thereby, as the head of a child, or other subject, which would take a skilful artist many hours to copy and enlarge by the unassisted eye and hand, could by the magic lantern means be copied more correctly in one quarter of the time.

[Here Mr. Skaife placed a photographic portrait on glass, the size of a small finger-nail, in the back of the pistolgraph,

* Read at the meeting of the Blackheath Society, April 15th, 1861.

then lighting his small lamp (the gas being turned down) an enlarged picture was perceived on the drawing-board screen, which was increased up to life size or diminished accordingly as the screen was slid backward or forward. Finally, adjusting the focus to about half life-size, he passed a small sable pencil charged with a shade tint rapidly over the distinctive light parts of the picture for a few seconds, then slightly turning the lid of the box upon which the magic lantern apparatus stood, the enlarged negative image appeared to slide off the sketch like a mask, revealing the progress of the sketch in contact with the parent negative standing close by.]

You see it is not necessary that the enlarging copyist should be a draughtsman in the artistic sense of the word, although before the mere photographic imitation can rank as a work of art, the mesmerising hand of an artist must pass over it.

THIRD REPORT OF THE EXPERIMENTAL COMMITTEE OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.*

Mr. Davis's Collodio-Albumen Process.

This formula is described by those of the Committee who have tried it as being extremely simple and certain, producing the best results, although at a trifling loss of sensitiveness. By thoroughly washing the film in common water Mr. Davis concludes that every particle of the free nitrate is either removed or converted into an insoluble salt of silver; so that on the application of the preservative no combination of silver with albumen is formed. Intensity is secured by the addition of glucose.

The Particulars of Manipulation, as given by Mr. Davis, are as follows :—

In the second communication from the Experimental Committee a formula was was given for a sensitizing solution which I found to work very satisfactorily when added to a suitable plain collodion. I will, however, take this opportunity of remarking, that any collodion that combines with an appropriate mechanical structure, the capacity of giving an abundance of half tone, is equally suitable for this as any other dry process. The plate after having been covered with such a collodion is to be excited in the usual 35-grain nitrate of silver bath, and then to be washed freely in a dish (or otherwise) with two or three quantities of common filtered water. In cases when the ordinary water contains organic impurities, it will be found preferable to wash with a very dilute solution of chloride of ammonium in distilled water. The film is now to be covered with the following preservative mixture :—

Albumen	1 ounce
Ammonia	10 minims
Glucose	¼ ounce
Water	1 „

Dissolve the glucose in the first instance in the water, next filter, and then add it to the albumen, previously well beaten or otherwise frothed. This preservative solution will keep for a lengthened period, and after having been prepared for a few days, will readily filter through common filtering paper. This latter operation should be repeated immediately before applying it to the plate, the liquid should then possess the brilliancy and appearance of amber-coloured collodion. Pour the first quantity along one edge of the plate, allow it to flow towards the other in a continuous wave, and pour off from one of the corners; recover with a second quantity, which should remain thereupon for about a minute. The plate is then to be washed freely with water, and stand on end to dry.

Gelatine Process.

This process is capable of producing good results, but it is not so generally a favourite with the Committee as those previously described.

Particulars of Manipulation.— Well wash the excited plate and then coat with a solution of gelatine, made by dissolving 80 grains of gelatine in a pint of water, and boiling down to half the quantity, filtering, and when cooled a little, adding 1 oz. of alcohol. This solution must be heated upon being applied, which is most conveniently done by standing the bottle containing it in a jug of warm water.

The Tannin Process.

From this process having so recently come before the public, the Committee have not had opportunity to test it to the extent they desire. Mr. Davis remarks respecting it, "The simplicity and readiness with which the latent image can be developed commends it to a full experimental consideration. The necessity of rendering the film sufficiently adherent to the glass when working upon medium size (10×8) plates without complicating the process; and the lengthened exposure required under the same conditions, over the obvious difficulties to be surmounted in connection with this process." Mr. Borchert recommends a five-grain solution only, as he considers the tendency of the film to wash away to be less in that case than when using a stronger solution of tannin. He adds "all preparations containing tannin (as leather) are very apt, in a dampish atmosphere, to engender fungus. This will have something to do with the keeping qualities. I have noticed marks of fungus in old gelatine plates although they were put perfectly dry into the boxes."

Pending the publication of the promised treatise, by Major Russell, the Commmittee reseve their opinion on this process, only adding the following remarks by Mr. Hannaford :—" Collodion for tannin prints may be of two directly opposite kinds.—The first, and probably the best, partakes of the 'mealy' nature to a very great extent, almost approaching to rottenness; this sample will be found to adhere to the glass with tolerable firmness. It should be strongly bromidised, and the alcohol and ether should contain as much water as possible.

"The second collodion may be of directly the opposite character. I have prepared a sample giving good results, which is so firm that the film can almost be lifted from the glass without breaking. It contains but a small quantity of water and very little bromide. This sample on being varnished round the edges, will bear a considerable amount of washing."

Particulars of Manipulation.—Thoroughly wash the sensitized plate, so as to remove every trace of nitrate of silver, coat with solution of tannin, 5 to 20 grains to the ounce. Dry as usual.

There is so much in this process that is promising, that the Committee propose giving it a fair practical trial during the coming summer months.

General Processes.

The Committee having now entered at some length into those processes which they consider the best, it will be sufficient, perhaps, to allude but shortly to some others which have been placed before the public from time to time.

The malt, glucose, linseed, raspberry syrup, metagelatine, &c. processes are each capable of yielding good results, but are severally open to the objection that the preservative media do not assist in retaining the collodion film in contact with the surface of the glass.

The resin process, from its extreme simplicity, is well worthy of attention. It has not yet received sufficient trial from the Committee to be spoken of with certainty.

Concluding Remarks.

In this report the Committee have given what in their experience has proved the best formula in the several dry processes which they consider will be most generally followed.

As a body they are inclined to give the preference, and recommend the Fothergill and Mr, Davis's processes; the tannin process, and Mr. Hannaford's modification of the Fothergill, they consider promising, but would at present more particularly call the attention of the experimental Members of the Sociefy to them.

* Continued from p. 183.

During the summer months the Committee purpose continuing their experiments in the preparation of extra sensitive plates. They, however, only attempted to report on the good working process, from which the Members of the Society may make a selection, now that the season for outdoor work has commenced.

PRINTING BY DEVELOPMENT.

BY LYNDON SMITH.

The last number of Photographic Notes contains a communication from Mr. Lyndon Smith, detailing some modifications he has made in the process of printing by development. He states at the outset that he mainly uses the formulæ of Mr. Sutton, the chief difference being the substitution of pyrogallic for gallic acid. He proceeds as follows:—

First, then, as to the paper. I obtain the best results on Canson's Positive, but Turner's Calotype gives good prints. Immerse the papers in this solution.

Common salt	160 grains.
Hydrochloric acid	10 drops.
Rain water	20 oz.

Let them soak some hours, that the acid may act thoroughly. On no account omit the acid, it is essential to success with Canson's paper; if you use Turner's you may omit it. Excite by floating on a bath (in yellow light of course).

Nitrate of silver	50 grains.
Citric acid	1 „
Water	1 oz.

Allow the paper three minutes, then hang up to dry, suspending with American clips—*not pins*—by *two* corners; put a slip of blotting paper along the bottom. Let the paper become *surface* dry, and while it is still damp, place in contact with the negative as usual, and expose to light till there is a faint image, give, say 3 seconds in full sunshine, and 90 or 100 seconds in dull weather, till experience shows you the exact time, which varies with every negative. Return to the dark room and develop as follows:—Turn up the edges of the print and make it into a tray, and lay it on a sheet of blotting paper; then in a clean measure-glass put a sufficient quantity of the solution,—say 1 oz. for a 10×8 print.

Pyrogallic acid	2 grains.
Citric acid	1 „
Water	1 oz.

Take the measure-glass in the left hand, and a glass triangle in the right, and pour the solution smartly down one side of the tray, and with the triangle spread the liquid cleverly all over the paper; this operation requires some practice, for if not performed neatly, the picture will be stained, just as a collodion negative would be. The picture developes very quickly, in about the same time as a collodion negative, and must be *closely watched*. If all is right, the deep shadows come up first, and strengthen considerably before the half tones and finer details of the high lights show themselves; as soon as it looks vigorous and powerful enough—recollect the fixing *does not reduce the print at all*—take hold of the tray by two corners, and turn the developing solution into the waste pan, and wash the print well under the tap, then fix in

Hypo soda	1 oz.
Water	1 pint.

letting the proof remain 20 minutes or half an hour in the bath; afterwards wash as usual; though I don't wash *as usual*, for I douse the print with a heavy stream of water from a piece of India rubber tubing attached to the tap, where I have a heavy pressure. I squeeze the tubing between my fingers, so as to make the water *fizz* out—I can't explain better—and direct the stream on the print which lies on the bottom of the wooden sink, turn it over repeatedly, let it soak half an hour, repeat the dousing, then take it out and dry. I think this is just as effectual in getting rid of the hypo, as soaking many hours, which softens the paper and dims the picture.

I have now detailed a process of printing positive photographs, at once simple and elegant; the proofs are as vigorous and powerful as could be desired; they can be turned out with great rapidity, and are of undisputed permanence; of their merits, artistically, I would rather leave it to you to decide. I will just make a few remarks on some points of the process. First, as regards the hydrochloric acid in the salting solution. If you try Canson's paper without the acid, it is almost impossible to get a clean vigorous print: it developes muddy, feeble, and bad in every respect: *with* the acid there is a marvellous difference; it seems to have opened the pores of the paper, and cleansed it from impurities, so that the picture comes up as bright and clear as it was dirty and feeble in the other case. But I cannot agree with you that the acid does not affect the delicacy of the proof, for I fancy it roughens the surface somewhat. I have tried lemon juice in the silver bath instead of citric acid, but cannot see any advantage in it. The *quantity* of acid in the bath is of the utmost importance: with *none* at all you cannot control the development: with too much there is no half-tone; therefore it is of importance to be careful in the addition of acid to the silver bath, and it seems as if great differences of tone and quality may be got by regulating the acid according to the density of the negative. This is a point that requires further working out. Care must be taken to keep the silver bath up to the proper strength. The development is a beautiful operation, the picture seems to spring out. I like printing now as much as I detested it before, for it is not a mechanical process as the common method is, but one which requires judgment and skill to conduct properly.

[We may remark that we have seen a print produced by Mr. Sutton, from a very fine negative by Major Stuart Wortley, by Mr. Smith's modification. The colour was good, and the print, whilst wet, was very rich, but sunk considerably on drying. This might be due. Mr. Sutton observed, to the fact that he had used more citric acid than was given in the formula.—Ed.]

THE STEREOTROPE.

The following description of Mr. Shaw's stereoscopic thaumatrope was recently communicated to the Royal Society by Mr. Warren De la Rue:—

"This instrument is an application of the principle of the stereoscope to that class of instruments variously termed thaumatropes, phantascopes, phenakistoscopes, &c., which depend for their results on 'persistence of vision.' In these instruments, as is well known, an object represented on a revolving disc, in the successive positions it assumes in performing a given evolution, is seen to execute the movement so delineated; in the stereotrope the effect of solidity is superadded, so that the object is perceived as if in motion and with an appearance of relief as in nature. The following is the manner in which I adapt to this purpose the refracting form of the stereoscope.

"Having procured eight stereoscopic pictures of an object—of a steam-engine for example—in the successive positions it assumes in completing a revolution, I affix them, in the order in which they were taken, to an octagonal drum, which revolves on a horizontal axis beneath an ordinary lenticular stereoscope and brings them one after another into view. Immediately beneath the lenses, and with its axis situated half an inch from the plane of sight, is fixed a solid cylinder, 4 inches in diameter, capable of being moved freely on its axis. This cylinder, which is called the eye-cylinder, is pierced throughout its entire length (if we except a diaphragm in the centre inserted for obvious reasons) by two apertures, of such a shape, and so situated relatively to each other, that a transverse section of the cylinder shows them as cones, with their apices pointing in opposite directions, and with their axes parallel to, and distant half an inch from, the diameter of the cylinder. Attached to the axis of the eye-cylinder is a pulley, exactly one-fourth the size of a similar pulley affixed to the axis of the picture-drum, with which it is connected by means of an endless band. The eye-cylinder thus making four revolutions to one of the picture-drum, it is evident that the axes of its apertures will respectively coincide with the plane of sight four times in one complete revolution of the instrument, and that, consequently, vision will be permitted eight times, or once for each picture.

"The cylinder is so placed that at the time of vision the *large* ends of the apertures are next the eyes, the effect of which is that when the *small* ends pass the eyes, the axes of the apertures, by reason of their eccentricity, do not coincide with the plane of sight, and vision is therefore impossible. If, however, the position of the cylinder be reversed end for end, vision will be possible only when the small ends are next the eyes, and the angle of the aperture will be found to subtend exactly the pencil of rays coming from a picture, which is so placed as to be bisected at right angles by the plane of sight. Hence it follows that, the former arrangement of the cylinder being reverted to, the observer looking along the upper side of the aperture will see a narrow strip extending along the top of the picture; then, moving the cylinder on and looking along the lower side of the aperture, he will see a similar strip at the bottom of the picture; consequently, in the intermediate positions of the aperture, the other parts of the picture will have been projected on the retinæ. The width of these strips is determined by that of the small ends of the apertures, which measure ·125 inch; and the diameter of the large ends is 1·5 inch, the lenses being distant 9 inches from the pictures. The picture-drum being caused to revolve with the requisite rapidity, the observer will see the steam-engine constantly before him, its position remaining unchanged in respect of space, but its parts will appear to be in motion and in solid relief, as in the veritable object. The stationary appearance of the pictures, notwithstanding the fact of their being in rapid motion, is brought about by causing their corresponding parts to be seen, respectively, *only* in the same part of space, and *that* for so short a time that while in view they make no sensible progression. As, however, there is an actual progression during the instant of vision, it is needful to take that fact into account—in order that it may be reduced as far as practicable—in regulating the diameter of the eye-cylinder, and of the apertures at their small ends; and the following are the numerical data involved in the construction of an instrument with the relative proportions given above:—

"The circumference of picture-drum $=22·5$ inches (A).

"The circumference of eye-cylinder $=12$ inches $\times$ 4 revolutions $=48$ inches (B).

"The diameter of apertures at large ends $=1·5$ inch (C).

"The diameter of apertures at small ends $=·125$ inch (D).

"While the large end is passing the eye, the picture under view progresses $\frac{1·5}{48}\begin{matrix}(C)\\(B)\end{matrix}$ of 22·5 (A), or ·703 inch.

"This amount of progression (·703 in.), if perceived at one and the same instant, would be utterly destructive of all distinctness of definition; but it is evident that the total movement brought under visual observation at any one moment is $\frac{·125\ (D)}{1·5\ (C)}$ of ·703 inch, or ·058 inch. This movement must necessarily occasion a corresponding slurring, so to speak, of the images on the retinæ; and the fact of such slurring not affecting, to an appreciable extent, the distinctness of definition, seems to be referable to a faculty which the mind has of correcting or disregarding certain discrepant appearances or irregularities in the organ of vision; as a further illustration of which I may cite the fact, mentioned by Mr. Warren De la Rue in his 'Report on Celestial Photography,' that the retinal image of a star is, at least under some atmospheric conditions, made up of 'a great number of undulating points,' which, however, the mind rightly interprets as the effect of the presence before the eye of a single minute object. That this corrective power is, as might be supposed, very limited, may be proved experimentally by this instrument; for if the small ends be enlarged in only a slight degree, so as to increase this slurring on the retinæ, a very marked diminution in clearness of definition is the immediate result.

"That form of the stereotrope, in which Professor Wheatstone's reflecting stereoscope is made use of, and which is better adapted for the exhibition of movements that are not only local but progressive in space, it is needless to describe here, because the principles it involves are essentially the same as those which are stated above.

WET COLLODION WITHOUT WATER.

BY COLEMAM SELLERS.

As an earnest advocate of the wet process—though an enemy of water to be carried up steep hills in a bucket—I hope all photographers will excuse me for forcing on them the results of my experiments in working the wet collodion process without the use of water in the field.

It is the custom of many operators to develop in the field, and, after a slight washing, to take the plates home to be cleared and strengthened. After the developer has been washed off, the plate may be allowed to dry and remain any length of time before clearing without injury. But if the iron be not washed off it will, in drying, crystallize and injure the film, also rust and make yellow stains. If there has been iron enough put on in the first place to decompose all the free nitrate of silver on the surface, the image will be developed, and the iodide of silver rendered insensible to light by the removal of the nitrate.

If now, after the iron solution has been poured off, we flow the plate with glycerine, it can be brought into the light, and, if kept in a horizontal position, the film will remain wet for several days, and can be finished at your leisure, as well as if fresh from the camera. Glycerine possesses the valuable property of being very slow to dry (if it will dry at all), is very soluble in water, covers the plate as a varnish, prevents the iron from oxidizing and penetrating the collodion, and destroys all tendency to peel up during washing and clearing. The iron solution I use is strong, being made of four ounces of proto-sulphate of iron; thirty-two ounces of water; one and a half ounce of alcohol. The amount of chemicals required to be carried for a day's work, where my glycerine process is used for stereoscopic photographs, cousists of four ounces of collodion; ten ounces of iron solution, as above; two ounces of acetic acid; two ounces of Price's glycerine.

A box should be prepared to hold the wet collodion negatives, so arranged with grooves that the plates can be carried in a horizontal position with the film side up. The only caution to be observed, is to drain off the iron solution before pouring on the glycerine, as the latter will be economised by so doing.—*Humphrey's Journal.*

Proceedings of Societies.

BLACKHEATH PHOTOGRAPHIC SOCIETY.

The annual meeting was held at the Golf Club House, April 15th, 1861, C. Heisch, Esq., F.C.S., the President of the Society, in the chair.

The minutes of the last meeting were read and confirmed. Messrs. H. Williams, and A. J. Melhuish were appointed auditors, and proceeded to examine the accounts while Mr. Skaife prepared his apparatus for illustrating his paper on a means of producing enlarged copies of pistolgrams or other small photographs.

After justifying the name pistolgram, which had been attacked in some of the journals, Mr. Skaife read his paper. (See p. 196.)

The Chairman said that Mr. Skaife's was one among many applications of what he thought a very important principle, viz., enlarging from small photographs; he had been giving much attention to that subject lately, not like Mr. Skaife, with a view of copying by hand, but for two purposes; one the enlargement of small pictures photographically, so as to do away with the necessity of carrying about large apparatus, and another which he thought would prove very useful for class-room illustration. It was often desirable to show microscopic objects to a class, of course this can be done with the oxhydrogen microscope; but when one or two only had to be shown in a lecture, this was not worth while. He had lately made some enlarged photographs of microscopic objects, printed transparent positives from them on dry plates, and then exhibited them in the manner Mr. Skaife had just done with his negatives by means of a lamp and a short-focussed portrait lens. He used a camphine or paraffin lamp with a bull's-eye condensor.

All objects of which satisfactory photographs could be obtained, even very moderately magnified (the number of which was, of course, very limited, as only very flat objects could be so copied), might be thus well exhibited. He had intended to exhibit some such objects to the society this evening, but he had been too much engaged to get them ready; he might mention that he had one of a louse, the original photograph of which was about one inch in length, and it could, with the lamp he had mentioned, be magnified to upwards of a foot without losing the smallest detail.

Mr. Melhuish asked if the Chairman thought enlarged photographs would ever rival in sharpness a really good negative, taken at once of its full size, he had never seen anything at all like this in an enlarged picture.

The Chairman said he thought if the enlargement were not pushed too far the pictures would lose nothing by the process. He believed a stereoscopic picture might be enlarged to a 12×10 without loss by proper management. One reason why many enlarged photographs were so wanting in sharpness he believed to be, that almost all who had tried it had used such long-focussed lenses: he had been using Ross's small single stereoscopic lenses, turned, of course, hindside before, and he hoped soon to produce some enlarged negatives, quite as sharp as any taken originally of a large size. He believed the best plan was to let the direct light of the sky fall down through the negative or rather through a transparent positive printed by superposition from the small negative, and not to attempt to work with direct sunlight, which made more complicated arrangements necessary.

Mr. Melhuish asked what time the Chairman thought it would require to take such an enlarged copy as he had mentioned. In all his (Mr. Melhuish's) attempts at enlargement the time required had been so great as to render the process practically useless, when the lens had to be stopped down sufficiently to give anything like sharpness.

The Chairman said he could not say very positively, but he thought from three to five minutes at the outside.

After some further discussion a vote of thanks was tendered to Mr. Skaife for his paper, and the Chairman proceeded to read the annual report of the society, which was, after a short discussion, adopted. The report was as follows:—

REPORT OF THE COUNCIL.

In presenting this their Fourth Annual Report, the Council feel that they have cause both for congratulation and regret. They can congratulate the society on its financial prosperity, as is shown by the balance sheet appended, while the subjoined list of communications made to the society during the past year will amply prove that the interest of the meetings has been well sustained.

Mr. Hardwich on the "Present State of our Knowledge of Photographic Collodion"—Mr. Wheeler on the "Solar Spectrum in its Relation to Photography"—Mr. Glaisher on "Pretsch's New Process"—Some "Remarks on Fluorescence" by Mr. Wheeler—"Remarks on Toning," by Mr. Heisch—Mr. Heath on the "Production of Direct Transparent Positives on Glass from Objects in Relief"—"Further Remarks on Toning," by Mr. Heish—Mr. Heath on "Manipulation in the Field"—"Remarks on Transparent Printing on Albumen," by Mr. Negretti.

Various interesting photographs have from time to time been exhibited, and special mention may be made of the transparent views of Windsor Castle and the other palaces, exhibited by Mr. Heath, and those from Java, Japan, &c., exhibited by Mr. Negretti. Two prints, the one by Mr. Heath, the other by Mr. Heisch, are also ready for presentation to the members for 1860. During the past year but little that is strictly new has been accomplished in photography; but, on the whole, the character of the pictures produced is more artistic than formerly. The experiments of Bunsen and Kirchhoff on spectrum analysis, though not made with relation to photography, may ultimately have an important bearing on the subject, specially with regard to the kind of artificial light best adapted for photographic purposes, by pointing to those substances whose flames appear in the most refrangible part of the spectrum. While speaking thus cheerfully of the past, the council regret that they cannot look forward with equal satisfaction to the future prospects of the society.

Circumstances have deprived the society of the assistance of some of its most effective members, several having left the neighbourhood, and others having been prevented by the pressure of professional engagements from taking any active part in its proceedings.

The number of working members being thus so greatly reduced, the council feel that they cannot carry on the affairs of the society in such a manner as to maintain the position it has so well won, even by taxing to the utmost the few who remain. Under these circumstances, they think it desirable to recommend the suspension of the periodical meetings, at least for the present.

They would hardly advise the entire breaking up of the society, as occasional meetings might be held when there is any subject of special interest to bring forward, and should any number of active photographers hereafter come into the neighbourhood, the periodical meetings could at any time be resumed without the formation of a new society.

In the mean time, the council would recommend that no subscriptions be for the present collected, and that the affairs of the society be entrusted to a committee who should be empowered to continue the subscription to the journal out of the balance in hand, and to call special meetings when considered desirable.

The Treasurer's account, showing a balance of £32 5s. 10d., was brought up and reported correct by the auditors.

Messrs. C. Heisch, G. Glaisher, H. T. Wood, and T. B. Wine, were appointed a committee to carry out the recommendations of the report, and the meeting adjourned.

South London Photographic Society.

The usual monthly meeting was held on Thursday evening, the 18th inst. F. F. Statham, B.A., F.G.S., in the chair.

Several specimens were contributed to the portfolio of the society, amongst which were an exquisite soft portrait of a sleeping child, by Mr. Fitch, landscapes by Mr. Howard, excellent specimens of the Fothergill process, a successful reproduction of one of Paton's paintings just sent in to the Royal Academy, by Messrs. Smyth and Blanchard, and some very delicate card portraits by Mr. Wall, the negatives produced by the intensifying process described in the beginning of the present volume of the Photographic News as successfully practised by Mr. Lacy.

The minutes of the previous meeting having been read, Messrs. Dennison and Chadwick were elected members of the society.

Mr. Hannaford then read the report of the Experimental Committee. (See pp. 182, and 197.)

Mr. G. Wharton Simpson handed round for inspection some very fine stereo negatives by the turpentine waxed-paper process, which had been forwarded to him by the Rev. J. Lawson Sisson, of Lausanne. He remarked, that as the question of dry processes was before the meeting, these specimens would be interesting as illustrating the amount of delicacy and perfect definition attainable in waxed paper. The exposure was only two minutes with a half-inch stop.

Mr. Sebastian Davis asked what was the focus of the lens with which the negatives were taken. It appeared to him probable that a double combination had been used; if so, the amount of definition and depth of focus the negatives showed appeared sufficiently perfect to admit of such lens being used with perfect success. He thought that in seeking a rapid dry process, the aid of the optician, in producing rapid lenses, was an element of importance to look to.

Mr. Simpson believed that a small portrait combination had been used.

Mr. Howard said he had no doubt whatever but portrait lenses had been used, but the definition was certainly exquisite. He had practised for a whole season with a pair of Jamin's combinations, but had found great difficulty in getting sufficient depth of focus; probably with some of the new lenses better results might be obtained, and rapidity at the same time. He was much interested in Mr. Hannaford's modification of the Fothergill process, and thought it likely to prove of great importance. For the purpose of a comparative estimate he had prepared four plates, one by the Fothergill process, as usually practised; then one fully washed before and after albumenizing; next one not washed at all, and finally one by Mr. Hannaford's modification. He exposed them all five minutes under similar conditions, the Fothergill plate was under-exposed, and so was the one fully washed. That by Mr. Hannaford's modification was fully exposed and a good picture, and the plate not washed was nearly a good one, but somewhat stained. He thought that the possession of the sensitive compound, ready mixed in due proportions, was a most important thing, on account of the immunity from stains. Altogether Mr. Hannaford's modification was a move in the right direction, both in simplifying manipulation and guaranteeing good results.

Mr. Borchert had once tried a similar method, but whilst he found that sensitiveness was increased, he found that keeping properties were destroyed. The preservative solution itself decomposed after keeping a few days, and the plates would not keep more than a week.

Mr. Hannaford remarked that if these plates would not keep, neither would the Fothergill plates, because the same conditions existed in each, the only difference that in the Fothergill process the compound formed was a little more uncertain. In his method the silver was not added in excess, but only in proper proportions. It was, in fact, Fothergill simplified in manipulation, and rendered more certain in result. Instead of forming a salt of silver on the plate, it was formed before pouring it on. All considerations as to the exact amount of washing were settled. It was only necessary to first thoroughly wash, pour on the solution, and then thoroughly wash again. However successfully the Fothergill process had been practised for stereo negatives, it was an undoubted fact, that for large plates, such as 12 in. by 10 in. that process, except in the hands of the most careful operators, did not give good results. The salt of silver found on adding the albumen solution was irregular from the different action between the solution and the silver at the first point of contact, and by the time it had covered the plate, stains and irregularities of deposit were the consequence.

Mr. Borchert said that when the solution was prepared as Mr. Hannaford had described, he quite agreed as to the evenness of result obtained, but he did not see in that case how the sensitiveness could be increased.

Mr. Hannaford said that an increase of sensitiveness was not claimed, but simplicity of preparation and evenness of result. There was the simplicity of the tannin process without the risks of that process. Various salts of silver might be formed in the albumen solution, but he had not mentioned them because he had not tried them. In reference to the Fothergill process he might remark that the pictures which had been presented to the poltfolio that evening would show how in the most careful hands stains would occur which rendered it necessary to black out the skies.

Mr. Howard suggested that the most common cause of stains was the commencement of decomposition, which was generally at the edges of the plates.

Mr. Sebastian Davis said the reference that Mr. Hannaford had made to the exhibited pictures printed from the Fothergill negatives, accompanied by the inference that the existence of the white skies has been caused from a necessity of concealing some unevenness of intensity in the plates, called for the acknowledgement that such had been the case. He had already referred in the report under consideration to the great difficulty of obtaining a film that would yield equal intensity upon development when prepared according to the ordinary Fothergill process. This difficulty arose from the all but impossibility of producing an even distribution of nitrate of silver over the whole of a large sized plate, by the dilution of the stronger solution. The simple fact of having to incline the plate so as to allow the albumen mixture to flow rapidly over its surface necessarily caused an accumulation of nitrate of silver towards one end of the plate. Under these circumstances an excess of the insoluble albumino-nitrate of silver compound becomes instantaneously fixed in the body of the collodion film, and this accumulation was incapable of being equalised by any amount of subsequent washing. He had therefore aimed at the avoidance of this impediment to success by introducing a preservative solution which permitted the free nitrate of silver to be washed away, without the reduction of sensibility to the material extent that would occur with ordinary dilute albumen, under like circumstances.

Mr. Hannaford observed that in Mr. Davis's process the danger of stains was obviated by entirely removing all free nitrate of silver at the outset, and plates so prepared would be as clean as could be desired. At first glance it might appear that the entire removal of the silver would render it difficult to get sufficient intensity, but the conditions necessary to produce vigour were restored by the action of glucose.

Mr. Hughes asked how long Mr. Davis's preparation (a bottle of which was on the table) would keep.

Mr. Davis said three or four weeks in the warmest weather. The ammonia preserved it.

Mr. Hughes remarked that he had anticipated that, and presumed that so long as it was alkaline it continued all right.

Mr. Davis: Yes.

Mr. Hughes said he had noticed that even when decomposition had commenced, by filtering and then adding ammonia, the solution might be restored and kept a long time. Refering to the tannin process, and its alleged weak point, the film leaving the glass, some diversity of opinion existed on the subject. He knew one gentleman who had been experimenting with it, who had tried no less than fourteen different kinds of collodion, and had not found one which readily left the glass. This gentleman, he might observe, used twenty grains of tannin to the ounce. Mr. Hardwich had stated that he never found the film give way. Major Russell, the inventor of the process, recommended that the plate should be the first coated with gelatine, but Mr. Hardwich had found that to be unnecessary. Mr. Sutton had experimented largely with this process, and he did not find this tendency of the film to give way.

Mr. Davis remarked that he believed that Major Russell was so convinced of the importance of gelatine that he intended to adhere to its use. The great objection to it and albumen was the tendency to throw the nitrate bath out of order. The use of albumen as a first coating for the glass he believed had first been recommended by Mr. Barnes.

Mr. Hughes said he believed the priority of suggestion belonged to the Rev. Mr. Laws.

Mr. Hannaford thought that the greatest objection to the use of any previous coating was that the great recommendation of the process, its simplicity, was destroyed.

Mr. G. Wharton Simpson remarked that so far as the nitrate bath was concerned, the albumen could be first coagulated by means of sulphate of iron and all injury to the nitrate bath thus prevented.

Mr. Hughes said the great merit of the tannin process was its simplicity and freedom from complication, and if the manipulations were multiplied its merits were largely destroyed. In its simplest form it was the nearest approach to the model dry process—a simply washed plate. The processes of Mr. Hannaford and Mr. Davis were in some respects similar, but the tannin solution itself was so easily prepared, that in that respect it took precedence of all preservative solutions. The rapidity with which it developed was also a great point, as it most nearly resembled wet collodion in that respect. It would be a great pity not to be able to use it without the bother of gelatine or albumen, which involved either the use of a separate bath, or previous coagulation of the film.

The Chairman suggested that a careful attention to the state of the glass when coated, to be sure that it was absolutely free from moisture, would be important.

Mr. Blanchard suggested that one cause of the tendency of the film to leave the plate was the different expansive powers of the tannin and collodion, when wetted.

Mr. Davis asked if any one had had any experience in the use of the resin process.

Mr. Clarke had tried the use of almost every resin and gum in the collodion. It was very rapid, but there was a great tendency to uneven development. Shellac he had found answered best. The details of his experiments were published in the Photographic News some time ago.

Mr. Hannaford had tried the use of gum elemi in the collodion, and thought the results so far promising. The chief faults he had found were stains arising apparently from the irregular draining of the plate. He asked if Mr. Clarke had tried a bath of salt water as a means of getting rid of the stains.

Mr. Clarke had done so, and the sensitiveness was so much lessened that he was unable to get a picture in as many minutes as it otherwise took seconds.

Mr. Wall announced that arrangements were in progress for a soirée at their annual meeting, and he would be happy to receive the names of gentlemen for the number of tickets they would require. His own paper "On Sharpness" would stand over until the next meeting, when also Mr. Sydney Smyth would read a paper "On the Solar Camera."

Mr. Thomas Clarke then read a jotting

ON THE STEREOTROPE.

Permit me to make a few remarks on the stereotrope exhibited at the soirée of the Photographic Society at King's College, on the 4th inst., and in which was shown some machinery in motion; on looking at which, I was immediately convinced of the impossibility of representing the steady progressive movements of machinery; for in this instrument, several pictures, taken at various stages of progression, are presented to the eye one after the other; whilst on the other hand, the image presented to the eye by the machinery itself, is, I may say, *one* ever changing picture, and not made up of distinct images; hence the jumping appearance which has already been described by Mr. Simpson, in the Photographic News; this I think can never be entirely overcome, it may be lessened to a considerable extent by multiplying the pictures, but not entirely overcome, from the beforementioned cause.

No doubt for some objects it will be very well adapted; objects in which distinct images are presented to the eye in succession, such as animals in motion, where one foot is placed before the other, and is actually at rest for a certain fraction of time, or the uplifting of a hammer, where two pictures would be found sufficient for the illusion, and a multitude of objects of this description may be very well exhibited.

There is also another point to which I would call attention, and that is, only half the picture was visible; possibly, however, this may be overcome by enlarging the aperture, as suggested by Mr. Shadbolt at the soirée. I do not wish by these remarks to at all depreciate the value of the discovery, or rather, the application of a known principle to stereography; on the contrary, I admit it to be very amusing and instructive, and it may be a useful addition to our inventions; but I do think it unadapted for representing such objects as machinery in motion. While upon this subject, I take opportunity of giving an idea of my own, with regard to stereoscopic views, viz., to obtain two panoramic pictures, at the proper angle for viewing them in the stereoscope, and mounting them on rollers, so that they may be viewed in the stereoscope as a moving panorama; I conceive the effect would be charming, and it might easily be accomplished by making a slide with four rollers, one on each side and two in the centre, these could be connected by a piece of silk, and made to turn by a handle at the the end similar to the frame used for the snow-storm in the magic lantern.

After the usual votes of thanks the meeting separated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 24th April, 1861.

On the 1st of August next the Exhibition of the Association for the Encouragement of the Industrial Arts in Belgium will be opened at Brussels. A section will be appropriated to photography, including proofs of scientific, technic, and industrial objects; artistic proofs on silver, plate-glass, &c.; works of art, antiquities, landscapes, portraits, artistic studies, &c.; photographic engravings, and the various applications of heliography. Exhibitors are invited to give a summary account of the nature of the negative process employed, whether collodion, wet, dry, or preserved, albumen, paper waxed or plain; any other particulars which it may be useful to add separately, for the information of the jury, upon the particular process, negative or positive, will be received with interest. The photographs must be protected by frames, passe-partouts, or form an album; it will be necessary to state whether the proofs have been touched or not. Each exhibitor will be allowed to send a dozen ordinary portraits, and a dozen card-size portraits, and no more. Coloured portraits will not be admitted. A committee will decide upon the admissibility of the pictures; such as have been previously exhibited in Belgium will be rejected. Prizes will be awarded to the most meritorious works exhibited, the distribution of which will be made publicly; they will consist of medals; such works as merit the distinction will receive "honourable mention;" the Association reserves to itself the right of making acquisition of the works exhibited. Persons intending to exhibit must notify the secretary, M. Dulieu, at the Palais Ducal, Brussels, before the 1st of June, by letter, post-paid, giving particulars as to the nature of the objects to be sent, the space required, in length, breadth, or height. The objects sent for exhibition must arrive before the 5th of July; they must be accompanied by the name and address of the exhibitor, and a statement whether he be the producer or the exhibitor merely; in the latter case, the actual producer should be specified, if possible. A note must also be sent to the secretary of the terms in which the articles exhibited should be described in the catalogue, together with the price, if for sale. Exhibitors must bear the expense of transmitting the objects sent, and also of their return.

The leaves of Indian corn, or maize, are now employed to a considerable extent in the manufacture of paper of good quality, superior in some respects to that obtained from rags; means have been discovered whereby the silica and the gum-resinous matters may be separated from the leaves. Two paper mills for the manufacture of paper from this source are now in operation, one in Austria, the other in Switzerland. The leaves contain naturally so much gummy matter that the pulp does not require the addition of sizing to fit it for writing paper: this gummy matter can be removed from the pulp if desired. The pulp is very easily and quickly bleached, if necessary, but its colour is so slight, that for many purposes bleaching will be found unnecessary. Maize paper is very strong, more so than paper made from rags. The machinery required for converting rags into pulp is not required for maize leaves, hence arises a notable economy in the process of manufacture.

Sea-weed has been recently adopted as a non-conductor between walls and roofs, to prevent sudden changes of temperature in dwellings. This material presents many advantages; it is indestructible, if kept in the dark: it does not harbour insects, it is uninflammable, and even serves as a check to combustion: enclosed between thin partitions, it serves, also, to check the propagation of sound. It has been tried in several kinds of wooden structures, and is found to answer so admirably that competent authorities recommend its extended judicious application. As it is hygrometric from the presence of saline matters, these must be removed by simply washing the weed in fresh water.

It has been found that vinous intoxication is an antidote to the morbid effects of the bite of venomous reptiles. The servant of a physician in the island of Manilla was bitten in the arm by a venomous snake: cauterization of the wound by a live coal was tried, but the symptoms of poisoning continued to manifest themselves in an alarming degree. The doctor then administered a bottle of strong wine: intoxication immediately followed, and the symptoms abated, but returned again as the influence of the wine passed off. A second bottle of wine was then administered, with salutary effect; then a third was given. Ultimately the patient recovered, exempt from all symptoms of poisoning.

Mr. Beauchamp announces the discovery of a new property of platinum, that of reducing perchloride of iron.

ALKALINE GOLD TONING.

Sir,—For some time back I have been making experiments in relation to gold toning. After trying a variety of different baths, and each one having some objection, I set about a series of experiments in search of a bath that would act as desired. I at last succeeded, after many disappointments, in producing a bath such as has long been desired. I will not enlarge upon its peculiar merits, but leave it to those who may try it, to whom I would feel obliged if they would communicate to me on that subject; the following is the formulæ:—

Chloride of gold	3 grains.
Acetate of potash	2 drachms.
Bicarbonate of soda	6 grains.
Nitrate of potash	20 grains
Water	7 ounces.

The proofs are first washed in common water. Then in the following bath:—

Chloride of ammonia	1 drachm.
Water	20 ounces.

Wash in plain water, then tone, and keep the bath to 70° Fahr. In a few minutes it will be done, wash well in warm water, and fix in hypo 25 per cent. I expect soon to communicate a new dry process, the preservative used is coffee. W. B. Fawcett.

Carlow, April, 1861.

[We have already had the [tapioca, rice, eggs, raisins, honey, sugar, candy, raspberry syrup, jelly, ale, porter, stout, wine, gin-and-water, and tea processes. Now we are promised the coffee process, and we heard the other day from a clever photographer that the best waxed paper negatives he ever saw were "waxed" with *dripping!* We hope shortly to see a new edition of Dr. Kitchener's "Cook's Oracle" adapted to the use of photographers. We look with interest for the coffee process.—Ed.]

HORIZONTAL STOPS.

Sir,—Oblong square diaphragms, similar to those described by your correspondent, Mr. Maginn, in your last number, were made to my instructions by Mr. T. Ross, on the 14th ult.

It would thus appear that improvements in photographic instruments do frequently suggest themselves simultaneously to various persons.

In my practice, the result has been the attainment of a degree of definition, absence of distortion, and depth of focus in the picture which, with the same lenses, I have previously never been able to attain.

Ocular demonstration being, however, better in these matters than mere words, I enclose for your inspection two pictures, perfectly untouched, taken with these new diaphragms, and am, sir, your obedient servant,

Lake Price.

London, April 21, 1861.

[The two large pictures (11 in. by 9 in.) which Mr. Price has forwarded, possess most excellent modelling and relief. We should have felt disposed to attribute much of this to careful lighting and artistic skill; but the statement that the same lenses could not be made to give equal results before meets such a suggestion. Coming from such hands we need scarcely add that the photographs are full of picturesque beauty. Such pictures can assuredly find no place under the head "machinery" in the International Exhibition next year.—Ed.]

THE TANNIN PROCESS.

Sir,—I beg to send you the following particulars of a simple and very successful way of working this process.

Coat with a bromo-iodized collodion (Hughes', Greenish's, and Ponting's answer excellently).

Sensitize in ordinary negative bath.

Remove to upright bath of distilled water, till the next plate is ready to take its place.

Then wash in a dish of ordinary water for half a minute.

Pour over the plate a few drachms of distilled water.

Coat with—

Tannin	20 grains.
Citric acid	1 grain.
Distilled water	1 ounce.

Pour on a sufficient portion of this to cover the plate, let it run off into the sink; pour on fresh quantity, and let it remain on for twenty seconds, then drain, stand up to dry, and when surface dry apply artificial heat (a stone bottle full of hot water answers well).

Give long exposure, twice as long as a Fothergill or Taupenot plate requires. Before developing, wet quickly under a tap.

Apply the following developer:—

Pyrogallic acid	2 grains,
Glacial acetic acid	30 minims.
Citric acid	$\frac{3}{4}$ grain,

with one or two drops of a 10-grain solution of nitrate of silver. Fix with hyposulphite of soda.

With ordinary care there is no fear of losing the film. I have developed plates that had been scratched all across without difficulty.

It remains to be proved yet whether this process is worth all the stir that has been made about it. I believe it is the cleanness and brightness of the development which dazzle the eyes of many, so that they do not notice the absence of those qualities which render albumen processes so valuable.—Yours, &c. J. G. C.

Photographic Notes and Queries.

Dark Tents.

Sir,—You would confer a favour on many of your readers, who, like myself, reside in the country and, consequently, have not the opportunity of seeing any new invention, by giving us a description of the best dark tent for the wet process in outdoor photography; Leake's and Smart's are often recommended, but I have not been fortunate enough to see a description of either.—I am sir, yours, &c. J. L.

Blencogo, Cumberland.

[A description of Leake's tent has appeared in the Photographic News and also in the Photographic News Almanac We intend to describe Smart's and some others shortly.—Ed.]

Albuminate of Silver in the Fothergill Process.

Sir,—The modification of the Fothergill process, detailed by Mr. Hannaford, last week, is, in my opinion, the best. I have tried the identical plan he recommends (*vide* Photographic News, Feb. 1), and find it is more sensitive, and more easily prepared. I have sent a negative for your inspection, not as a specimen of the *best* results, but as an average one.—I am, sir, yours, &c. Wm. B. Bartholomew.

Fareham, April 24, 1861.

[Our correspondent's letter will be found on p. 53 of the present volume, with the initials W. B. B. It will be seen that the suggestion is identical with that just made by Mr. Hannaford. The negative forwarded is of a fine red vigorous character.—Ed.]

Gallo-Citrate of Iron Developer.

Sir,—I see in your very valuable paper some remarks on developing negatives, and, as the exact method I make use of has not been noticed, I will, if you think proper to insert it, lay it before you.

I make a developer of from twenty grains per oz. of water, and another of two grains pyrogallic acid per oz. of water. Of each of these take equal quantities, and mix, which produces a thick muddy solution. Now add a saturated solution of citric acid, until the liquid becomes a clear green colour: add a little alcohol, about a half-ounce per pint. On proceeding to develop, flow just sufficient distilled water over the plate to cover it for two or three seconds, then return this to the measure, and add to it sufficient developer (about one and a-half ounce to a plate nine inches by seven inches), and develop with this. If the negative should look likely to become too dense before the details are well out, pour this away, and use the strong developer as it is: a little practice will determine whether this is necessary or not. Should you think this of any interest, you may insert it.—Yours, &c.,

Blaenavon, April 23*rd.* J. Burgoyne.

[This formula is as nearly as possible the same as that of Mr. Tunny, which we published a few weeks ago. The details of manipulation here given are good, and may be followed with advantage.—Ed.

Talk in the Studio.

Photography and Art.—Mr. Samuel Fry has recently been engaged in taking a series of negatives, 25 inches by 18 inches, and 10 inches by 8 inches, of the interior of the Great Western Station, engines, carriages, &c., for Mr. Frith, as aids to the production of his great painting "Life at a Railway Station." Such is the value of the photograph in aiding the artist's work, that he wonders now however they did without them!

Stereo Exchange Club.—A correspondent writes on this subject:—Regarding the Stereo Exchange Club—suppose A. be dissatisfied with B.'s picture in return for his, let both be sent to you, and then say, "We consider Mr. B.'s stereograph 'Grazing Cattle' decidedly good (or bad, as the case may be), and a fair (or by no means a fair) exchange for Mr. A.'s 'Scene on the Wye.'"

A New Application of Photography.—A circumstance recently occurred showing the great business utility of the modern discoveries of Photography and the Electric Telegraph. The Count de Penafiel left Lisbon for Paris, carrying with him an order for 70,000 francs; this, however, he unfortunately lost on the road, and telegraphed the same to his banker at Lisbon; that gentleman at once telegraphed to Paris stopping payment of the order, but sent by post the portrait of the Count de Penafiel, stating that the amount might be paid to him when he presented himself.—*Times.*

Pistolgrams of Babies.—Mrs. Arabella Araminta Angelina Smith, writing in *Punch*, has been horrified by an advertisement which she says is headed, in big type "Pistolgrams of Babies." "Good gracious, *Mr. Punch*," she adds, "pray what *ever* is a pistolgram? Is it some new-fangled fire-arm, like an Armstrong breech propeller, and can it be intended really to go *off?* If so, I'm sure *infanticide* will be alarmingly increased, and it will be a mercy if but one out of a dozen of one's babies is not shot. I know I've thought a pop-gun a sadly dangerous thing, and as for those toy rifles one now sees in every nursery, I'm quite sure that it's not safe for chilbren to be left with them; for though Charles says they can't be loaded, they've got great bayonets stuck on to them, such as seem made expressly to poke one's baby's eyes out. But what destructive implement a 'pistolgram' may be, I confess I really have not courage to inquire; only I feel *convinced* that if it be *one-half as terrible as its name seems to imply*, our infant population will be dreadfully decreased. I know I'll take good care that nobody shall buy my *ittle tiddleums* a pistolgram, unless I see quite clearly that it can't do any harm; and for my part I can't think why people can't use common English when they want to name a thing, instead of puzzling one with gibberish that no one understands. Yours abruptly, *Mr. Punch*, for *ittle tittleums is crying*." Arabella Araminta Angelina should visit Mr. Skaife's establishment, and she would find that, notwithstanding the startling name, some of the "pistolgrams" of babies are amongst the exquisite specimens of portraiture which the art has produced.

Fine Arts Copyright.—The Attorney-General's Bill gives to the author for his life, and thirty years after his death, a copyright in pictures, and works of sculpture, and drawings made, or for the first time disposed-of after the passing of this Bill; and this right is to extend to a copy of any work of fine art (lawfully made). The same copyright is also given to the authors of architectural works, (plans, models, etc.,) but when a building has been constructed no person is to be precluded by this Bill from making plans or models from the building itself, and constructing any building therefrom. The Bill includes works of fine art published abroad, and gives copyright in them; but no copyright will be acquired in any case unless the name or monogram of the author is legibly placed upon some conspicuous part of the work. Penalties imposed for all fraudulent productions, falsely pretending to be the work of an artist who is not the real author, or colourable imitations to be passed off as executed by him (whether there be subsisting copyright or not), and, though there may be no subsisting copyright in a work of fine art, no person (except the last proprietor of an expired copyright in it) may use the name of the author upon any engraving during his his life. The importation of piracy is actually prohibited.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

To Correspondents.

B. L.—We prefer freshly-made starch for mounting prints. If you can get them rolled or hot-pressed, or passed under the pressure of a lithographic or copper-plate press, so much the better.

Meta.—A view lens can rarely be used with anything like full aperture. For a lens of six inches focus, use a three-eighths stop.

A. B. S.—The best, indeed in many cases the only available method of printing life-size pictures by means of enlarging camera, is by the development process, details of which were given in our last in the "Dictionary of Photography." The sketch of the megascopic camera to which you refer was not enclosed.

C. D.—Call on Mr. A. H. Wall, 28, Old Bond Street, and state your case. He is the best teacher of colouring whom we know, and will probably be able to meet your wishes as to terms. Probably joining one of his classes would suit your purpose.

T. T. L. K.—The formulæ of the "Alabastrine Redeveloping Solution" and the "Alabastrine Varnish" are trade secrets. Various recipes for preparations intended to serve the same purpose have appeared from time to time in our pages.

Wm. Deane.—The spots appear to proceed from some salt in or on the film of the negative, which has probably not been well washed after fixing, and appears not to have been varnished.

J. C. B.—To get rid of streaks the acid must be added to the bath. Add three ounces of distilled water to one ounce of nitric acid. One drop of this will be equivalent to a quarter of a drop of nitric acid. You will find details of the method of printing-in clouds to a landscape photograph in Mr. Fry's paper, p. 350, vol. iv. of the Photographic News. We did not receive your card.

J. L.—The size of the condenser has nothing to do with the amount of enlargement; it merely governs the amount of light and consequently the time of exposure. The solar camera has a condenser of nine inches diameter and about seventeen or eighteen inches focus. We have heard of one with a condenser of twenty inches in diameter: it is quite possible to get any amount of enlargement with a very small condenser, or with none at all.

J. Sands.—We do not immerse the prints in ammonia and water in our own printing operations. It is not necessary to tone immediately if inconvenient, in an hour or two will do, but the prints should during that time be placed in successive changes of water.

B. C. W.—An abstract of Mr. Mudd's method of working the collodio-albumen process is given in the Photographic News Almanac. We shall publish shortly a fully detailed statement of his manipulations, results of his experience to the present time. See Report of the Experimental Committee of the South London Society, in our last and present numbers.

X. L.—We believe that it is decided that about 90 degrees are all should be included in a picture by the panoramic lens.

L. A. D.—Over exposure was probably the cause of the effect you describe in your negative. The best method of increasing the strength of a nitrate bath, is to fill it up from a stock solution of greater strength than the original bath.

H. Bellini.—We have referred to your letter in our first article.

J. B.—One thickness of black, and another or two of yellow calico, make a very suitable covering for a tent; with sufficient of yellow only, to make a window.

A Lady Photographer.—It is difficult to state the cause of the spots on your charming little picture. You appear to have tried the majority of remedies which meet such a case. Have you been sufficiently careful to have no dust in the camera, or elsewhere? Are the negatives intensified by any process? Can sulphur vapours, or sulphur in any form, come near your negatives? The spots are similar in appearance to those we have seen on Daguerreotypes and glass positives, produced by sulphur.

W. D.—We have posted the letter.

E. Smith, Bath.—We have received the two pretty card portraits you forward, and shall be glad to know the intensifying process by which they were produced. Your lens scarcely covers sufficient space, with a flat field, for standing figures, but in other respects the pictures are very good.

Carl Holt.—The firm you refer to is certainly in existence. The transaction to which you refer certainly appears unbusiness-like, and can only be excused by some such unaccountable combination of circumstances as the miscarriage of letters, &c. It is not a matter which we can refer to more definitely in these columns. We have had good paper from several firms, amongst which we may mention Rouch, Hughes, Hope, Sandford, Stereoscopic Company, and others.

J. H.—The use of an alkaline gold solution will afford no certainty of permanency unless the prints are perfectly fixed. We have seen several prints toned by the alkaline process, which were faded in greater or less degree simply from imperfect fixation. Perfect fixing in fresh hypo is quite as important as thorough washing.

L. M. N.—Negatives intensified by means of bichloride of mercury always require varnishing, as the contact with the mercurial salt would injure the sensitive paper.

A. C.—It is quite a matter of taste. We do not like a crowd of accessories in the background, in any kind of photograph, carte de visite or otherwise.

T. H. N.—The drab or India paper tint round photographs is printed by means of lithography on the mount. Cards so printed ready for use are to be had of some of the dealers.

Clenow.—The corners of the carriers in the dark slide are best made of silver wire, other metals soon corrode and become destroyed.

P, P.—It is impossible to say which is the best tone for a photograph, as tastes vary. There is, moreover, a sentiment in colour which may be made materially to enhance the suggestive character of the monochrome of the photograph. A warm light tone most readily suggests the fair blonde, whose complexion would be quite ignored by a dark black-toned impression. Whilst a picture of the latter character would exactly indicate the dark eyes and raven tresses of the brunette. So also in landscape the mellow effect of a sunset landscape would be suggested by a glowing warm-toned picture; whilst the leafless trees, and snow-covered ground in a winter scene, may, with propriety, receive a colder greyer tone. Use judgment in these matters.

F. Y. L.—Flatted crown glass may be used with advantage for positives; but for negatives it is safer to use patent plate, because of the chance of breaking in the pressure frame. If you use flatted crown for negatives, try each glass in the pressure frame before taking a picture on it.

A Photographic Tour in Wales will be continued next week

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 139.—*May* 3, 1861.

COPYRIGHT IN WORKS OF FINE ART.

We congratulate our readers on the probability that before the present session of parliament shall be brought to a close, the productions of our common art will, for the first time, we believe, receive legislative recognition as works of fine art.

We have already notified our readers that a Bill was recently introduced into the House of Commons by the Attorney-General, entitled "A Bill for amending the law relating to Copyright in Works of the Fine Arts, and for repressing the commission of fraud in the production and sale of such works." From the section devoted to the interpretation or construction of terms we find that the word "picture" shall include "every drawing, painting, PHOTOGRAPH, or other work (except engraving as hereinafter explained) which on a flat surface embodies any design, or represents any scene or object, by means of any process or material." From another clause of the same section we find that the word "engraving" shall be understood to mean "the embodiment of any design, or the representation of any work of fine art by any means or process upon metal, stone, wood, glass, or any other material whereby copies may be multiplied on flat surfaces." And finally a further clause declares that the term "work of fine art" shall include "every picture, work of sculpture, engraving, and architectural work."

The terms here employed, it will be seen, are most comprehensive, and in a variety of ways include photographs by every possible process within the provisions which follow. These provisions, are, we think, of a most satisfactory nature, and give the most complete and lasting protection to property in ideas and works of skill.

First, then, as to works embodying original ideas; the provisions of the Bill are as follows:—

"The author of every picture, work of sculpture, and engraving, which shall be made, or for the first time sold or disposed of, after the *commencement of this Act*, and his assigns, shall have the sole and exclusive right of copying, reproducing, and multiplying such work, and the designs thereof, by any means, of any size, and for any purpose, for the term of the natural life of such author, and *thirty* years after his death."

The intention of the Bill as regards Reproductions is stated as follows:—

"Every person who, after the *commencement of this Act*, shall lawfully make or cause to be made any picture, work of sculpture, or engraving, from or after any work of fine art, and his assigns, shall have the sole and exclusive right of copying, reproducing, and multiplying such picture, work of sculpture, or engraving, by any means, of any size, and for any purpose, during the term of his natural life, and *thirty* years after his death."

In order to bring any picture under the protection of the intended law a very simple expedient is necessary, and since this is very important, we call special attention to it. It is thus stated:—

"No copyright shall be acquired in any work of fine art, or in the design thereof, until the name or monogram of the author or maker thereof shall be legibly signed, painted, engraved, printed, stamped, or otherwise marked upon the face, or some other conspicuous part of such work."

The fourth section defines the extent and limits of the intended law as regards reproductions:—

"Nothing herein contained shall prejudice the right of any person to copy or use any work of fine art in which there shall be no copyright, or to represent any scene or object, notwithstanding that there may be copyright in a copy or imitation previously made of such work, or in some representation of such scene or object, as fully and amply as if this Act had not passed."

Other sections have reference to matters of detail, such as the mode of transfer of property in copyrights, the extent of retrospective action intended, &c.; but some of the most important clauses are devoted to the penalties incurred by an infringement of the copyright to be conferred by the Act. It is here provided that

"If the author of any work of fine art in which there shall be subsisting copyright, after having sold or disposed of such copyright, or if any other person not being the proprietor for the time being of copyright in any work of fine art, shall, without the consent of such proprietor, repeat, copy, colourably imitate, or otherwise multiply for sale, hire, or distribution, or cause, or procure to be repeated, copied, colourably imitated, or otherwise multiplied for sale, hire, or distribution, any such work, or the design thereof, or any part of such work or design, or after having received, either verbally, or in writing, or otherwise, from any source other than the proprietor of such copyright, knowledge that any such repetition, copy, or other imitation of such work or design, or any part thereof respectively, has been unlawfully made, or after having been served with, or had left at his premises, a written notice signed by such proprietor or his agent to the same effect, or by any or other means knowing or having reasonable or probable cause to believe that any such repetition, copy, or other imitation has been unlawfully made, shall import into any part of the British dominions, or sell, publish, or let to hire, distribute, or offer for sale, hire, or distribution, or cause, or procure to be imported, sold, published, let to hire, distributed, or offered for sale, hire, or distribution, or shall have in his possession for any or either of these purposes, any repetition, copy, or imitation of the said work, or of the design thereof, or of any part thereof, made without such consent as aforesaid, such person for every such offence shall forfeit to the proprietor of the copyright for the time being a sum not exceeding *one hundred pounds*; and all such repetitions, copies, and imitations made without such consent as aforesaid, and all plates, blocks, moulds, dies, negatives, and other things which shall be exclusively applicable for obtaining such copies, shall be forfeited to and be the property of the proprietor of the copyright."

In the following section it is provided that the imitation or forgery of the name, initials, or monogram of any artist upon a picture, with intent to defraud, shall be regarded as a misdemeanor, and punishable with imprisonment for two years, with or without hard labour. The penalties incurred for the infringement of copyright under these provisions are recoverable either by action or by summary proceeding before two or more Justices of the Peace having jurisdiction where the offender resides. It is provided, however, that no action or proceeding of any kind shall be commenced without notice in writing to the offender of at least one calender month; and within three months of the commission of the offence constituting the ground of proceeding.

From the extracts and the rough outline of the Bill we have given, it will be seen that the amplest protection is intended to be given to every form of property produced by the inventive brain, or skilful hand of the artist, whether he be sculptor, painter, photographer, or engraver. The Bill appears, in all respects, so far as we can judge, an admirable one. We must not, however, be too hasty with our pæans. It is, at present, only a Bill, not an Act: a "project of law," not an accomplished fact; and a score of proverbs rush on our memory to warn us of the slips that may yet occur. The end of the session is not yet; and the "slaughter of the innocents," so fatal to embryo laws, is not yet over. Of one of

Serjeant Talfourd's Bills, it is recorded that the House divided upon it twelve times in one day, and finally threw it out. The Bill has, however, by this time, been read a second time, and we hope shortly to be able to record that it has passed into law.

In this document, at least, the productions of the photographer are recognised as "works of fine art," notwithstanding the classification of Her Majesty's Commissioners for the International Exhibition of 1862. We shall have something to say on this subject shortly. We have abstained hitherto for reasons we shall explain.

PHOTOGRAPHIC EXHIBITION AT BIRMINGHAM.

WE beg to call the attention of our readers to an announcement in our advertisement columns, of the Exhibition in connection with the Birmingham Photographic Society, to be held at Aston Hall, commencing towards the close of the month. The town of Birmingham is largely identified in many respects with photography, and its Society numbers some of the best photographers in the kingdom. The medals to be awarded, of which there are six, embrace a new feature, we observe, two of them being devoted to the productions of the solar camera. It is somewhat unfortunate that the notice should be so short, we apprehend it arises from causes beyond control. We trust, however, that intending exhibitors will bear in mind the Spartan's motto —"If your sword be short, add a step to it."—and make up in exertion what is lacking in time. We hope the Exhibition will be in all respects a successful one.

The following are the published regulations:—

The Exhibition of the Society will be opened on Monday, May [illegible], 1861, and will continue open three or four months.

All descriptions of photographs will be admissible together with apparatus, &c., used in producing the same, or in any way connected with the art, as also photographic engravings, &c.

It is recommended that all pictures should be framed and glazed, and the margin of the mounting-board should not exceed three inches in width; but unframed prints will be allowed.

In the case of pictures of smaller size than 9 by 7 it is desirable that four or more should be placed in one frame; but no frame must exceed twelve square feet in area.

Each picture, or frame of pictures, must have the name and address of the artist and exhibitor distinctly written upon the back, together with number, which number must correspond with a list of the subjects to be inclosed with them, specifying the particular process, whether calotype, waxed-paper, or the different varieties of collodion by which the negatives were taken from which the pictures were produced, and, if for sale, the price.

Touched or coloured prints must be accompanied by an untouched copy.

The Society will award three silver and three bronze medals for the best pictures in the Exhibition. One silver for the best portrait or group; one bronze for the *second* best. One silver medal for the best photograph of any other subject, landscape, composition, or otherwise; one bronze medal for the *second* best. And one silver medal for the best photograph from the solar camera. The whole of the above to be pure [illegible] photographs. A bronze medal will also be awarded to the best coloured photograph from the solar camera.

The solar pictures to be of not less size than 21 by 17, and unless taken in Great Britain will be disqualified from competing for the prizes.

All works intended for exhibition must be delivered at Aston Hall, near Birmingham, not later than the [illegible]th day of May next.

Any picture received after the [illegible]th day of May will be ineligible for competition for the medals.

A commission of 1[illegible] per cent. will be charged on all sales made during the Exhibition.

A list of the photographs sent must be inclosed with them, and a duplicate forwarded to the Hon. Sec., together with such other particulars of process as the exhibitor may wish to communicate.

At the close of the Exhibition the pictures remaining unsold, or not for sale, will be carefully packed and returned to the owners.

Scientific Gossip.

ALTHOUGH cyanide of potassium is confessedly one of the most poisonous chemicals with which the photographer can deal, cases of fatal poisoning produced by its means are fortunately very rare,—so much so, in fact, as to lead some persons to doubt that it is an active poison at all. A case of poisoning has, however, recently occurred in a photographer's family, which presents several points worthy of notice; and the extremely rapid action of the poison cannot fail to serve as a warning to all who are in the habit of handling and leaving about this salt. The unfortunate victim in this case was a servant in a photographer's household, and the following notice, which is condensed from the official report of the case, will explain the circumstances which led to the fatal result. The deceased was 17 years of age. The evening before her death she had appeared slightly indisposed, and went to bed without taking any supper. In the morning she came down apparently well, and had breakfast, but refused to take any dinner. Up to four o'clock in the afternoon she did her household work as usual, when she was sent by her mistress into the portrait-room (immediately adjoining the dark room in which the chemicals were kept) to light the fire. She returned in a few minutes, and busied herself in getting the tea ready. Her mistress's attention was now attracted by her extraordinary attitude. She stood with a fixed stare, face twitching, and her hands hanging down from the wrists, as if paralysed. Her mistress ran to her, caught her in her arms in the act of falling, and put her in an arm-chair. Now followed a severe attack of general convulsions, with froth from the mouth and nose, supposed by witnesses to be an epileptic seizure. Some brandy was then administered, of which she swallowed a little with difficulty, and appeared for some time to be rallying. The convulsions, however, returned. She suddenly stiffened her legs, gave a few gasps at long intervals, and died. The attack seems to have lasted about twenty minutes, during all which time she neither spoke nor screamed. It appears, also, that the period from the time of her taking the poison—*i. e.* when she was sent into the portrait-room—till she was first seized, could not have exceeded ten minutes; so that the whole period, from taking the poison till death ensued, was between twenty-five and thirty minutes. Some additional evidence was elicited at the inquest, viz., that she had had a quarrel with her lover the evening before, and that one of the lumps of cyanide in her master's stock bottle was observed to have had a portion recently broken off. The deceased was first seen by a medical man when she had been dead about half an hour. A *post-mortem* examination was made forty-one hours after death; and fifty-two hours after death a chemical examination of the contents of the stomach was made by Mr. E. R. Southby. The contents of the stomach, amounting to about four ounces, consisted of a grayish viscid fluid. The reaction was slightly alkaline. About two ounces were acidulated with sulphuric acid, and distilled in a glass retort till about half had passed over. During the distillation, the smell of prussic acid was perceptible, but a good deal masked by the stench. About one drachm of the distillate was boiled with a little sulphide of ammonium, till the smell of the latter had disappeared. On the addition of a few drops of sesquichloride of iron, the deep red colour of the sesquisulphocyanide of iron appeared, this colour disappearing completely on addition of a solution of bichloride of mercury. Another drachm of the distillate was rendered slightly alkaline by solution of potassa, a small crystal of protosulphate of iron added, and the whole boiled: a drop of sesquichloride of iron solution was then added, and the mixture acidulated with hydrochloric acid. A blue colour was produced, disappearing on addition of solution of potassa in excess, and reappearing on acidulating with hydrochloric acid. On standing for twelve hours, the Prussian blue was deposited. The residue left in the retort was evaporated to dryness, ignited till a greater portion of the carbon was driven off, and digested with hot distilled water and the solution filtered. On addition of hydrochloric acid, alcohol and bichloride of platinum, a yellow crystalline precipitate was formed, which was seen under the microscope to consist of octohedra of the double chloride of platinum and potassium. The above leaves no doubt that the poison taken was cyanide of potassium. We hope this will act as a warning to careless photographers. Such a poison as this should never be left where it could fall into the hands of ignorant persons, or those with criminal intentions. Many instances are on record of the terribly fatal action of this poison:

prussic acid, in fact, is as poisonous when combined with potash as when in the free state. Thus, two grains and a half of the pure salt are equivalent to one grain of anhydrous acid, or fifty minims of the acid of the London Pharmacopœa. Cyanide of potassium may therefore be regarded as a solid, containing prussic acid in its most concentrated form, no less than 39·3 per cent. by weight. A dose of three to five grains of the pure salt may, therefore, easily destroy life; and, in fact, less than five grains of the commercial cyanide, which is known to be very impure, has been known to be fatal, death having taken place in a quarter of an hour. In case of this poison being taken by accident, by any of our readers, solution of protosulphate of iron (positive developing solution) should be instantly swallowed in large quantity. No time whatever should be lost in taking this antidote, as the symptoms of poisoning occur with such rapidity and violence that there is scarcely time to employ treatment. The sulphate of iron is the best antidote known; and this, taken instantly, would have the effect of decomposing the poison, and converting it into Prussian blue; but if many minutes be allowed to intervene, the blood becomes poisoned, and then no chemical antidote can reach it. The best treatment, next to administering sulphate of iron, is to give an emetic, and to pour cold water on the head and along the spine, from a considerable height. The vapour of ammonia may likewise be applied to the nostrils; but, unless the patient be treated very early, there is little chance of recovery from a large dose.

The subject of the temperature of the toning bath has been more than once mentioned as being of importance to the proper colouring and fixing of the prints, but we are not aware that any accurate experiments have ever been undertaken on this point. Talking, a few days ago, with one of the best photographic printers we know, he stated that he considered the secret of his invariable success was in always regulating the temperature of his toning bath to a certain degree. He uses a bath consisting of one pint of water, six ounces of hyposulphite of soda, and three grains of the double chloride of gold and sodium. This is to be kept at a temperature of from 120 to 150 degrees Fahrenheit and the pictures immersed in it. In less than ten minutes the prints are perfectly fixed and toned to a rich, velvety black colour, with brilliantly clean whites free from any yellow, cheese-like appearance. The bath is kept hot by a very simple contrivance; a tin vessel is made sufficiently large to allow the porcelain toning dish to fit tightly into the upper part, leaving about two inches space between the bottoms of each. Two circular apertures are made in corners of the tin vessel, one to allow of fresh water being poured in to replace that lost by evaporation, and also to allow of the escape of steam, and the other to admit of the introduction of a thermometer. Hot water is poured into the tin vessel to within half an inch of the bottom of the porcelain dish, and is kept at the proper temperature by being placed on two large, flat, oblong iron weights, previously made hot in the fire.

Notes and Jottings.

No. 6.

Modification of the Fothergill Process.

When communicating to the Experimental Committee of the South London Photographic Society the result of some researches made in dry plate photography, we were not aware that a modification of the Fothergill process, which we then suggested, had previously been proposed, in these columns, by Mr. Bartholomew. So far as concerns ourself the idea was solely arrived at by considering what took place during the preparation of a Fothergill plate.

We have now made further experiment in the same direction, so as to be able to place before our readers more definite particulars of manipulation. General instructions serve very well for the more experienced photographer; but there are many amateurs who prefer having clear and full information on minor details. We therefore add the following "jottings" to our former communication.

It is very desirable that the preservative solution should contain a defined amount of silver, and, therefore, as ammonia is of very different degrees of strength, we have found it preferable to take nitrate of silver in certain proportion, instead of adding it so long as the precipitate would dissolve, as we formerly proposed.

The method of preparing the albumen solution we now prefer, is as follows:—

To the white of one egg add three ounces of water and about ten or fifteen drops of ammonia. Beat this in the usual manner until perfect limpidity is obtained, and then add a drachm of a thirty grain nitrate of silver solution (a portion of the bath will serve). A milky precipitate will be formed, which should be re-dissolved by the addition of ammonia, a few drops at a time, in just sufficient quantity to render the liquid clear, or, preferably, slightly milky. We have some solution a fortnight old, prepared thus, as good as when first made.

Any "dry" collodion may be used. After removal from the bath, thoroughly wash under the tap, or in a large quantity of water,—this cannot be too effectually done,—and then drain perfectly. We may here mention that the plate should be *completely* drained; for if any quantity of water remains, the albumen solution will not readily mix with it, and thus markings from uneven action are likely to arise. If the albumen contains a large excess of ammonia, this danger of stains is got rid of, as the solution in such case readily mixes with water; but the reason why we do not prefer ammonia in excess will be given presently. The plate thoroughly drained should be coated with albumen, which should be poured off and on two or three times, and then allowed to remain for a few minutes whilst the preparation of another plate is gone on with. Lastly, it is to be thoroughly washed, drained, and spontaneously dried.

As the albumen solution undergoes no alteration, excepting that of getting slightly diluted; it may be used over and over a great number of times. An ounce will be sufficient for a dozen stereoscopic plates.

Excess of free ammonia in the preservative solution has a tendency to dissolve out certain organic silver salts, which are formed in the film when old collodion is employed. This loss weakens the intensity, and unless the action be equal at all points, uneven development will result. We therefore find it advisable not to have ammonia in excess in the albumen. Michael Hannaford.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Chef d'Œuvre.—A French term, used to indicate a work of art possessing the highest excellence, as such; and sometimes to express the most excellent production of all an artist's works. We may thus speak of a picture as a *chef d'œuvre* of painting; or a statue, as a *chef d'œuvre* of sculpture; and of any single production as any particular artist's *chef d'œuvre.* Thus I regard the print by Mr. Mudd, which, as a member of the South London Photographic Society, I have just received, not only as a *chef d'œuvre* of Photography, but as Mr. Mudd's, also. (Beg pardon: the secretary will peep out sometimes, you know.) The Italian *Capo d'opere* is sometimes used to express the same meaning.

Chiaroscuro.—An Italian term, used to define the judicious arrangement or management of a picture's "*lights* and *darks.*" I use the words "*lights* and *darks*" advisedly, although the distinction between these and "light and shade" may appear but trivial. In connection with chiaroscuro, the photographer should learn to consider as "light," not only light proper, but the whole scale of tones which are not allied to darkness. For instance, he must regard a pale surface as light, even if it be really in shade; and an illuminated surface as *dark*, if it be really so in tone or colour (see *Breadth*). Hence it follows that, when considering this subject in connection with our selected picture, we should first examine it on the ground-glass, calculating the tones as light or dark in accordance, not only with their real appearance, but also with reference to colour in its relation to actinic influence.* By so doing, we acquire a nearly instinctive appreciation of the real value and importance of *chiaroscuro*, and discover, almost at a glance, the pictorial qualities of our subject. The operator, however, will never produce fine examples of effective *chiaroscuro* without understanding thoroughly the photogenic influence of the various colours in nature. It has been recommended to study this subject, by photographing the colours of mere pigments, and arranging a scale of the effects thus obtained; but although for the purpose of copying tinted drawings or paintings such a scale might be exceedingly useful, it would be of little real service in photographing from nature, when not only are colours subject to the varying influences of the quality of light, the character of surface, and the nature of the reflexions,† but the different actinic powers are frequently of a seemingly contradictory character. As a general rule. we may *approximate* to the desired effect by considering that red, orange, and yellow, either when pure, or forming the predominating elements of any other colours, tend more or less to produce "*darks;*" while colours belonging to the more chemically active portion of the spectrum tend, in similar degrees, to produce "*lights:*" but the true artist, aware of the extreme value of his picture's tones, in reference to *chiaroscuro*, will not be satisfied with information of so comparatively vague a character.

Chiaroscuro is one of the most important things in the expression of sentiment. In some pictures, the slightest touch of pure white would destroy all their feeling and sentiment; and others owe their wonderful effect purely to the entire absence of all the darker tones. Photographers seldom recognize this important fact, although they have sufficient command over their materials fully to secure these artistic and poetical effects. One operator's pictures may possess a well-arranged scale of tones between white and black; and another, we will say, possesses a different but equally beautiful scale, ranging between white and a tone short of black; while a third may ignore white, and revel the Rembrantesque effects of broad deep darks and shadows with subdued lights of a faint pale grey. But the mischief of it is, that each operator produces *one only* of these styles, and that without any reference to the nature of the subject, or the sentiment or poetry which should be embodied therein. The wildest scene from the most gloomy, rugged, and solitary of spots, or a group full of mournful and sombre interest, receive from the hands of such photographers just the same treatment as a bright piece of sunny landscape in a richly cultivated country; or a gay smile-moving episode of merry children's cheerful spring. Not only is this peculiar to mechanical manipulators in photography, but we see the same results produced by those of their number whose artistic capabilities and acquirements would lead you to hope for better things. Why is this? simply because photography is not yet regarded as one of the fine arts, because the scientific elements of the discovery have so thoroughly absorbed all the intellectual and mechanical efforts of its votaries that the pictorial has been thoroughly and completely neglected. Until the publication of the articles on "Chiaroscuro and Composition" by Lake Price in these pages, I do not think the slightest attention had been directed by any of the photographic journalists towards the practical application of the rules of art to photography.

Light and shadow well managed not only express infinitely more than is imagined by many, but will very pointedly suggest colour itself. A recent writer on art, speaking of photographs, pointed out how "even in the most perfect of these philosophical productions, a certain amount of pictorial effect is wanting, and a deficiencey is felt of that concentration of interest caused by a more artistic application of the rules of chiaroscuro."* How common it is to see photographs made up of a mass of monotonous tones scarcely varying in intensity throughout; having neither contrast, variety, nor effect; flat, poor, and weak; but still showing that a simple movement of the camera to the right or left would have brought in just enough of the lighter or darker tones to have produced a very brilliant and striking effect; and so converted an uninteresting patch of flat and sombre-hued paper into a picture of objects in relief surrounded by space, and full of pictorial interest. The most important elements of chiaroscuro will be found in the realization of the effects given by the atmosphere and by reflected lights, and in securing a focus of light to attract the eye, and a focus of dark which may give it increased brilliancy, all such considerations being, however, subservient to, or rather embodied in the idea of "*breadth.*"

H. Ottley, in his "Points of Criticism"† says "The observer of nature, whoever, in short, has paid attention to the different aspects of the same landscape when contemplated at different seasons of the year, or at different hours of the day—in bright and cloudy, or in damp and moist weather respectively,—need hardly be told how much the effect of a picture depends upon the quality, character, and direction of the light which is supposed to pervade it."

* See some articles on "Colour, in its Relation to Photography," in the 4th Volume of this Journal, especially that in the 93rd No.

†A colour—say in drapery—which is extremely non-actinic in its character, may be improved for your purpose by reflecting upon it a strong light of some colour which is chemically active, or, on the contrary, a too actinic colour may receive reflected light of a reverse character.

* George Barnard.

ON PRINTING TRANSPARENCIES.

BY SAMUEL FRY.

It is scarcely possible that there can be one of my readers who has not been struck with the vast difference between the two methods employed at present for producing positive proofs from the stereoscopic negative. Great as always must be the pleasure of inspecting a really good proof, when printed of a rich warm colour, and on highly albumenized paper, the result is not to be compared with what might be produced from the same negative when printed by superposition on a prepared glass plate. I would not pretend to assert that the means of doing this involves no more trouble and care than printing on paper; but it is contrary to all experience to find that in any of the affairs of life the best results are obtainable without giving the utmost attention.

In my own hands, the simple processes I am about to describe have been productive of the most pleasing pictures, many of them from negatives which, when printed on paper, were very unsatisfactory. These processes have not been communicated to more than a few persons, each of whom have succeeded perfectly in producing proofs from their own plates, in many instances rivalling the finest productions of French photographers; and I feel, therefore, no hesitation in strongly advising my readers who have time, and who really wish to obtain the best proofs their negatives are capable of giving, to at once adopt it. It is no small recommendation to transparent printing to say that negatives, far too weak and transparent to print on paper, will, on glass, give positives of very great vigour: those who have seen the writer's published transparent stereograph of the sea, No. 3, entitled "A Sou'-wester," may judge by that of its capabilities. At the time the picture was taken, a heavy gale was blowing up from S.W., during the March equinoctials, and the sea was running higher than is often seen at Brighton, the sun being obscured by heavy vapours. After repeated trials, under the most disadvantageous circumstances, I succeeded in producing the negative from which the prints in question were obtained; and though, amongst the large number printed for sale, I am well aware there are some few copies which, from their want of vigour, should not have been issued, yet by far the large majority possess much greater density than the original negative; and several photographers capable of judging, who have seen the plate, strongly doubted, previous to printing, its power to produce strong proofs.

Although these processes may seem to involve much detail, and may, on perusing, seem complicated, yet it will be found, in practice, to occupy less time than the description requires. The following are the divisions into which I propose to separate the whole—Preparing the plates, Drying, Exposing, Developing, and Mounting.

I shall describe in detail, even at the risk of being rather tedious, the three methods I practise, giving with each the peculiarities of the pictures produced thereby. As will be remarked, the increase in the apparatus and chemicals of the photographer required for glass printing is so slight as to be within the means of all.

The three substances I have in turn adopted, to form the preservative coating over the plate, are all well known to the readers of the Photographic News. They are albumen, gelatine and oxymel; and as each produces a picture, having its own characteristics, I will explain, for the benefit of intending experimenters, what my experience of the result of each is, as a guide to its adoption or rejection. I first commenced with oxymel, using 1 dram thereof to 4 oz. of distilled water, applied in the manner hereafter described. When dried quickly before the fire, or in a tin box, with external heat, these plates become quite dry, smooth and comparatively hard. The picture developes up very rapidly, and acquires a rich, almost blue tone, with great vigour and transparency. This is peculiarly suited to weak negatives. The only fault of the process is that, from the hygrometric properties of the infinitesimal quantity of oxymel (honey, water and acetic acid), the plates are liable, if kept long, to become rather soft in damp weather, and thus, during the close contact of printing, small particles, like pin points, are taken off, leaving transparent holes. The remedy is, to keep them in a tolerably warm room after preparation.

The second plan is by gelatine. Plates thus prepared require careful wetting after exposure, as gelatine being slowly soluble, the developer would otherwise be tardy and unequal in its operations. Gelatine is easily applied, develops cleanly and slow, and acquires ultimately a good, rich, sepia tone, dependent to some considerable extent on the quantity and character of acid present during development.

The third plan is albumen, and is, in fact, equivalent to the collodio-albumen plates in their first state, using plain; instead of iodized albumen. Of the three I think I give the preference to the latter, as producing the richest tones and best general effect; but the negative, to bear printing by it, must have an extremely hard glossy surface, and not be touched up with colour, except where inevitable to conceal spots, as the albumen has a considerable tendency to adhere to such places, or indeed any part of the negative, and pull off small pieces, which process by no means augments the subsequent value of the negative. To sum up, to print a wet collodion negative on glass, I suggest the use of oxymel, or gelatine, as not so destructive to the plate; but where the plate is the result of a dry process, and therefore possesses the hard surface usually given thereby, I should say use the albumen process, which I will now describe. I recommend a collodion of rather spongy nature, which when rubbed up by the finger powders or crumbles up, rather than a tough contractile film, which often contracts in drying, and either cracks off or spoils the picture by distortion. Where a collodion specially made for dry plates is not at hand, it is very useful to mix any good negative and positive collodion in equal parts, and use the mixture. I have often by this means produced extremely good results.

It is of great importance to have the collodion perfectly free from specks or floating particles of any kind, in fact, if anything, it is even more important than in taking negatives, as every blemish is here brought so palpably before the eye, and cannot be obliterated. For this process the only addition to the photographer's apparatus is two baths of stereo size placed adjoining the nitrate bath. The latter preparation is exactly the same as used for negatives, nearly neutral, quite clean from floating particles, and fully up to 30 grains to the ounce. I need scarcely say that where the negatives to be printed are taken by a binocular camera, it is necessary to cut them in halves before commencing, and to fasten the halves *round* on a stereoscopic glass, adjusting them in the stereoscope to their proper position, and being careful to obtain the best stereoscopic effect. It will be found that thin-flatted crown glass answers perfectly for transparencies, though the original negatives are of course on patent plate.

The albumen preparation is thus made:—

Pure albumen	1 oz.
Aq. dist.	6 oz.
Am. fort.	30 minims

Agitate them well together, and after twelve hours settling filter through a sponge. In addition to the usual nitrate bath, have a bath, stereoscopic size, of distilled water close at hand. Collodionize, as usual, but allow the film to set for one minute before immersion: on removal from the bath, in three minutes, set up the plate, corner ways, to drain into a glass, and meanwhile immerse another plate in the nitrate bath. I find it of some importance that the upper corner of the plate should rest, while draining, against a sheet of glass placed for that purpose against the wall, as both during draining, and also the subsequent final drying, any woodwork, or even sometimes paper, appears to cause markings on the plates.

When the plate has sufficiently drained (in three or four minutes) remove it to the distilled water bath, and work up and down until the oily appearance of the surface is entirely gone. When this is accomplished, hold it under a stream of common water, either from a tap or a jug, and wash it thoroughly, back and front. Having drained slightly, pour on at one corner a drain of the albumen mixture, and work it well to all parts of the plate, then wash off again with common water, giving it a considerable quantity on all parts of the plate. Now set aside to dry, standing on a glass or small gallipot into which it may drain, and the upper corner touching only glass, as before directed.

If the temperature of the room is not below 50° the plates will dry spontaneously in an hour or so; but if they are wanted for immediate use, a hot-water box may be used with great advantage. I employ such an one for Fothergill's and other dry processes with the best results.

The sides and bottom of this tin box are made double, on the principle of the hot water dish, and hot water is poured in by the funnel at the end. When the plates have ceased to drip, they are placed in the box face to the side, on blotting paper, and the lid shut down, they will then become thoroughly dry and hard in a few minutes, the steam passing off through a ventilator in the lid.

I find these albumenized plates for printing keep for any length of time, often six months, being as good as ever. My practice is to keep my stock of dry plates in mahogany grooved boxes, in which they undergo no deterioration. The surface is extremely hard, and if the collodion be well formed they are as clear as opal glass.

(*To be continued.*)

ON THE NEUTRALIZATION OF THE NITRATE OF SILVER BATH BY CARBONATED ALKALIES.

BY T. A. BARBER.*

Some three or four years ago I recommended oxide of silver

* Read at a meeting of the North London Photographic Association, April 24, 1861.

for correcting free nitric acid in the exciting bath: this and the carbonate of silver are the only additions that can be made to effect the object and at the same time preserve its integrity. It is, however, found in practice that there are many combinations of nitric acid which are not injurious, so this method is rarely adopted, the alkaline carbonates having the preference, as, being always at hand, they are the most convenient.

It is not my object in broaching this subject to condemn the use of alkalies, but just to point out a source of error that may arise from using the carbonates.

Carbonic acid gas is to some extent soluble, or rather it is tenaciously held in combination by aqueous solutions, so that when we add a carbonate to an acid it is only after waiting till the gas escapes or is driven off by heat that the fluid becomes in a fit state to receive the test paper. One of the best illustrations of the power of carbonic acid to redden litmus paper in the presence of an alkali is that of dipping it into a newly-opened bottle of soda water; the reaction is the same as if dipped into vinegar.

I recollect once reading in the list of "Answers to Correspondents" in *The British Journal of Photography*, a reply to one who had been adding carbonate of soda at the rate of a drachm to a pint of bath, without being able to neutralise the acidity. Now this was very likely to have been the fact; but the acid that changed his test paper was no doubt carbonic acid, which he had not allowed to evaporate before seeking advice. This applies in some measure to all cases when a carbonated alkali is used, more or less apparent according to the proportion of acid originally present.

Carbonate of silver is also open to the same objection, nor does it very readily part with its carbonic acid. I have exhausted my patience in endeavouring to dissipate the acid reaction on litmus paper by adding this carbonate. The remedy is, of course, time, or boiling the solution: we then get a bath absolutely neutral.

Wanting the oxide, I should recommend the caustic alkalies as preferable—it matters not which: ammonia forms no exception. There is no danger of spoiling the bath by an overplus; for, although it may be made alkaline, this alkalinity is in no case due to the adjunct, but to the formation of free oxide of silver, which, after filtration, is easily corrected. In fact, the point of saturation is passed when turbidity commences, and whether the bath be acid or alkaline it is immediately available to test paper.

The alkaline acetates are sometimes used to correct free nitric acid, but are open to the objection that there is no knowing when the decomposition is completed, and we have to guess as to whether we leave nitric acid or form more acetate of silver than we intend.

The objection to the employment of oxide of silver for neutralizing free acetic acid applies equally to the use of carbonate of soda: acetate of silver is formed in both instances—directly by the oxide, and indirectly by the latter. The soda unites with the acetic acid, forming acetate of soda, then double decomposition follows with this and the nitrate of silver, resulting in nitrate of soda and acetate of silver.

It has been recommended of late to use recrystallised nitrate, as being the purest form of obtaining it. Formerly the fused was said to be the best. There is no doubt that the oftener you repeat the process of crystallisation, each time rejecting a portion of the mother liquor, the purer will be the result. This method is necessarily much practised in organic chemistry, but is quite inexcusable when dealing with nitrate sf silver.

My advice to photographers is to buy their nitrate as cheaply as the competition of manufacturers allows them, and doctor it themselves with oxide. This, with the influence of light, will free it from both acid and organic matter, leaving a solution purer than is attainable by any other means. Let them also bear in mind that recrystallisation is no guard against sophistication.

SPECIFIC GRAVITY OF NITRATE OF SILVER SOLUTIONS.

BY GEORGE DAWSON, A.M.

Table for ascertaining from the Specific Gravity to the nearest grain the amount of Nitrate of Silver contained in one fluid ounce of pure solution, at 60° Fahrenheit.

CORRECTIONS FOR TEMPERATURE.—For every 10° above 60° add 1 grain; and for every 10° under 60° deduct 1 grain.

[This table was presented and explained at the meeting of the North London Photographic Association, on the evening of Wednesday, April 24th, in completion of the valuable labours of Mr. Dawson in the analysis of silver solutions. Its object will be best understood by a reference to Mr. Dawson's former papers in our columns, and to the reports of recent meetings. We may state, however, that the table gives accurately the precise quantity of pure nitrate of silver in a measured ounce of the solution, for all strengths, from 10 to 140 grains, the usual sources of error having been eliminated by careful experiment and calculation.]

MOUNTING PHOTOGRAPHS.

BY THOMAS GULLIVER.

Amateurs and others only requiring to mount a print now and then often find it inconvenient to prepare starch paste in small quantities; but the following mixture, when once made, will keep for months ready for use. It is smooth as oil, easy to prepare, does not thicken, and will stick like glue; it also has the advantage of not cockling the prints so much as the ordinary starch paste—

Picked white gum-arabic	½ oz.
Dextrine	2¼ oz.
Liquid ammonia	4 drops
Water	8 oz.

The gum arabic is to be pounded in a mortar, and mixed with the dextrine; then rubbed in the mortar, with two ounces of the water, till quite smooth; then the rest of the water added, and boiled in an enamelled saucepan for ten minutes. When cold, it may be put into a wide-mouthed bottle, the ammonia added, and thus kept for use.

17, *Heathfield-street, Swansea.*

Dictionary of Photography.*

Prism.—The prism used in optics is a triangular piece of glass, which decomposes a ray of light passing through it, and produces the prismatic spectrum.

Process.—The term process is a very common and useful one in photography, and describes the entire formula and manipulations used in producing any distinct class of pictures, as the "positive process," and the "negative process"; or any distinct method of producing similar pictures as the "dry collodion process," and the "wet collodion process."

Protosalts.—Various metallic bases combine with oxygen and other elements in different proportions, and the prefix *proto*, meaning first, is applied to those combinations in which one equivalent of the base, and one equivalent of oxygen, or other element, are united. Thus protoxide of iron contains one equivalent of oxygen, and one equivalent of iron. The term protoxide would naturally suggest that it was applied to the first combination which could be formed; this is not always done, however, in practice, as where the combination contains less than one equivalent of oxygen, the term suboxide is used. The highest binary compound of the same element is distinguished by the prefix *per;* thus the peroxide of iron contains the largest amount of oxygen which combines with that base. As the developing powers of the protosalts of iron exist in virtue of their affinity for oxygen, it follows that as soon as they are satisfied by acquiring all the oxygen with which they can combine, and become peroxidised, the developing power ceases. The same prefixes are used to indicate the same combinations of metallic bases with other elements, such as chlorine, and hence we have subchlorides, protochlorides, and perchlorides, &c. The exact proportions of other combinations are indicated by other prefixes, into which it is unnecessary here to enter.

Pyrogallic Acid.—This is a substance with which the photographer is very familiar, having been for many years the chief developer used in the negative processes. Although styled an acid, it is neutral, and does not redden litmus paper; it forms no salts. It is formed by exposing gallic acid to a temperature of from 410° Fah. to 420°, which produces decomposition, and a yellowish white sublimate of white lamellar crystals is formed, which is pyrogallic acid. It is very light, and easily soluble, either in water, alcohol, or ether. From its affinity for oxygen, it is valuable as a developer, acting with less energy than the protosalts of iron, but giving a more organic deposit, and is thus valuable in the production of negatives. The aqueous solution soon becomes discoloured from the absorption of oxygen, and loses its developing power. A concentrated solution in alcohol, if kept carefully stopped, will retain its efficacy some months.

Pyroligneous Spirit, known also as pyroxylic spirit, wood alcohol, and wood naphtha, is a substance resembling alcohol in many respects, but belongs to the methyl series, and is obtained by the destructive distillation of wood. It is miscible with water, alcohol, and ether: its specific gravity at 60° is ·800. It is neutral to test paper, and permanent in the air. It has a strong pungent taste and smell, which renders it easy to detect in the smallest quantities. It is used, in connection with photography, for burning in spirit-lamps, as a solvent for varnishes, and, indirectly, very largely in the manufacture of collodion.

Its use in the manufacture of collodion arises from its presence in "methylated spirits." To explain this, it is necessary to state that the heavy Government duty on pure alcohol renders it an expensive article for use in the manufactures. To meet the difficulty arising from this, as a check to trade, a method was devised for removing this heavy duty on alcohol intended for chemical and manufacturing purposes. To guard against the application of untaxed alcohol to drinking purposes, it was enacted, some years ago, that alcohol might be sold free of duty, provided it was mixed with ten per cent. of wood spirit, the pungent odour and taste of which would render it unfit for use in any way, as a beverage. It may be purchased so in quantities of not less than twelve gallons, the purchaser giving security for its being applied to its legitimate purposes, and undertaking not to retail it except in combination with some gum: shellac,—at the rate of an ounce to the gallon is prescribed, we believe,—its use as a solvent for varnishes and French polish having been chiefly contemplated.

Large quantities of ether, sold as methylated ether, are manufactured from methylated spirit; and this ether, and the spirit itself, is used extensively by manufacturers of collodion, by the makers of the cheaper sorts especially. Much discussion has arisen, at different times, as to the propriety of its use, and the influence it had on the character of the collodion. Mr. Hardwich came to the conclusion, after some experiments, that whilst an excellent collodion might be manufactured from it, the stability was less than when pure spirits were used. Instability, insensitiveness, overdensity, and a tendency to throw the nitrate bath out of order, have been the chief objections alleged against the use of methylated spirits. And these charges have been supported as necessary, from the fact that the worst samples, both of alcohol and of wood spirit, were used in preparing the commercial methylated spirits. On the other hand, the addition of a small portion of pyroxylic spirit to collodion made in the pure alcohol, used at one time to be commonly recommended, for the purpose of preserving its sensitiveness. This notion probably arose, however, from the property this spirit seems to possess, especially in the presence of a bromide, of preventing the darkening of collodion from the presence of free iodine, as it grows old.

Where the methylated ether and alcohol can be obtained pure, we see no reason to believe they exercise any deteriorating influence whatever on collodion, and the various bad effects which have been attributed to these solvents for pyroxyline, have most probably arisen from the use of impure samples. Methylated spirits, highly rectified, and doubtless freed from much of their impurity, can be had of a specific gravity of 805 at a much less cost than pure spirits, as usually sold 56 or 60 over proof, that is of a specific gravity of 840 or 830. We have used the methylated alcohol ourselves, for various purposes in connection with photography, for some years, without having in any instance detected any injurious result. Those photographers who are however anxious to avoid its use, may readily detect its presence in any sample of collodion by dropping a little on the hand and rubbing it for a few seconds. The smell of alcohol and ether will soon evaporate and leave the characteristic pungent odour of the methyl, which is much more persistent in remaining.

Photographic Tourist.

PHOTOGRAPHIC RAMBLES IN WALES.—No. 2.*

BY J. H. JONES.

AFTER leaving Morristown behind me for about half a mile, at a sudden curve in the road I came to a group of thatched cottages, which appeared so piquantly beautiful in their rustic simplicity, that I must, perforce, stop to take a view of them; the ivy climbing up in all directions over them, and then spreading over the roofs, added a charm not often to be met with.

Crossing the canal at this point, which was near a colliery, I walked along the towing-path for a short distance, and stopped again to take a view of the canal, which at this point presented a picture in which the light and shade were so harmoniously blended, that it surpassed anything I had ever met with on a canal side; the stunted trees on the western side drooping downwards to the water, to which several coal barges were moored, formed the foreground, while the middle was occupied by a small ivy-covered bridge, through the arch of which another bridge could be seen in the distance, while the light streaming through the trees on the side of the towing-path threw the light and shade about in a manner which beggars description. There are several other nice little "*bits*" to be had between this and the second bridge mentioned above, at which point I regained the road.

Following this road I passed Fountain's Hall, which has some pretensions to architectural beauty; the road is lined for a considerable distance with trees, which form a very agreeable shade from the heat of the sun, and at the same time gives it a very rural aspect: passing onwards, I came to a village called Buildings, near which, on the right hand side, by a gate, there is a delightful scene; right below me was the canal, and by the side of it was the river Tawe, which, rolling over its pebbly bed, sent up such a murmuring, babbling noise, which struck most musically on the ear, while the cottages and farms dotted here and there the lovely green meadows, in which cattle and sheep were quietly grazing, and the hills rising up in stately grandeur and stretching far away in the distance, formed the background, and made the scene at once picturesque and beautiful. Soon after leaving this village I found myself at Clydach, and just after passing the reading-rooms, and about the centre of the village, a charming view presented itself; immediately in front of me was a cluster of cottages, built on the sloping banks of the river, while a little to the right was a rustic wooden bridge thrown across the canal, and to the left a small bridge across a minor stream, and in the centre a large three-arched stone bridge, at the back of which were the ruins of an old mill, while the water coming down from the hills at the back rushed foaming along over its rocky course; Clydach Church, a little further on, is rather a pretty one for a village church, but being very modern I did not stop to photograph it. From this point until I reached the outskirts of Pontardawe, my walk lay through a perfect avenue of trees, and tastefully cut hedgerows. Near the Mason's Arms, on the right-hand side of the Pontardawe road, as I entered the village, there was a gap in the edge, and not wishing to lose anything that could be seen, I entered it; and here I found another view which appeared so very nice in the declining sun that I determined to secure it; the field in which I found myself sloped gradually to the canal side, which was strewed here and there with barges, whose long, black, slender forms cut sharp and clear the bosom of the canal they rested on, while below them on the marsh between the canal and river, a tin-works, with its numerous flues, and behind them the river, which was spanned by a graceful bridge of one arch, near which stood an old elm-tree, whose giant form seemed like the "spirit of the scene," while, beyond the bridge, the flat, green fields vanished away in the distance; and on the opposite bank to where I stood was the Pontardawe railway and station, and above that the village of Alltwen, whose numerous white cottages speckled the hill, like a field of daisies; as soon as my plate was exposed I passed on, entered the village, and looked about me for quarters for the night. Early the next morning I was out in search of the local beauties of the village, and the first object which attracted my attention was the church (Eglwys Newydd) whose tall and graceful spire glittered in the early morning sun; it is so placed that it can be seen from any point in the village; I, therefore took three distinct views of it, the first from a lane on the east side, the second from the banks of the canal; in this view I had what some would call a perfect medley, first, there was the canal, then a bridge, a considerable portion of the village, and then the church itself on an eminence behind; the third view was from a field on the west side; as soon as this was finished I made a closer inspection of it, the work on the exterior surpasses anything of the kind to be met with in a country village; the interior gives several most beautiful pictures; as I entered the doorway, which is directly under the belfry, and turned to my left, I was in raptures, the beautiful pillars springing from the tesselated aisles, and running up for forty or fifty feet, and then uniting in gracefully carved arches, while at the far end of the church was the chaste and tastefully carved pulpit, reading-desk, and font, all in white stone, and further on an exquisitely beautiful screen of the same material in front of the choir, lit up here and there by the sun streaming in through the western windows; only one thing is wanting to complete the beauty of this graceful church, and that is the insertion of the painted window in the chancel, which, from what I have heard, will soon be done. After making pictures of all I wished here, I left this sacred edifice and returned to Nature's own temple, whose floor is the green and beautiful earth, whose pillars are trees, whose roof is the blue and glorious sky, and whose choristers are the birds, whose tuneful throats sing praises to *Him* who made all things beautiful.

Turning up a lane opposite the Cross Inn, I soon came to Cwm Dû (Black Glen). Turning aside from the lane proper I followed one which descended to the brink of the stream, a tributary of the Tawe: here indeed was a pretty scene, a small waterfall some two hundred yards from where I stood appeared, owing to a curve in the stream above the fall, to rush out of the foliage which clothed the banks of the dingle, and coming down with many a twirl and eddy, ran on its never ceasing course; with here and there a tree covered with moss bending over the water, whose branches seemed like giant arms, longing to embrace the stream, which laved its roots, and supplied it with nourishment; a cottage built on a jutting piece of rock some forty or fifty feet high, seemed like the palace of the fairy who presided over the scene below; while in the background, the waving corn might be seen clothing the hills to their very top. After impressing the image of this view on a plate, I retraced my steps until I reached the point of my deviation from the lane.

I now ascended the hill for a mile or so, until after passing Gellyonen House, I came to a style, crossing which, I found myself in a narrow pathway, which led in a zigzag direction to the bottom of the glen, another portion of the one mentioned above, which cannot be reached by any other way; I stopped occasionally on my way down to photograph some studies of fern and bits of rock, which appeared here and there, so unusually beautiful in the light which streamed through the foliage; that they were really irresistible. There is one view, about half way to the bottom, which particularly struck me as interesting, through an opening in the trees, which appeared to be made on purpose, a stream of water rushed over the rock which formed the other side of the dingle, which being rather steep, made a fall of considerable beauty, the foliage on both sides of the

* Continued from p. 190.

dingle being of a diversified character, added to, rather than detracted from its merit.

When I gained the bottom of the footpath, I found myself on a bed of pebbles, with here and there an immense boulder, which had, no doubt, in years gone by, been torn from the wall of rock which faced me, where I stood, but which was now, by the continual force of the stream, rounded off, and appeared like huge pebbles, the wall of rock from which they had been torn was now hung with creeping plants from whose pendant branches water was continually dropping. Turning a little to the right, the stream was seen to come round a curve in the glen, with such force, as plainly indicated to the eye, as the noise did to the ear, that a fall of some magnitude was close at hand. The scene from where I stood was indeed one of more than ordinary beauty; the dingle on both sides, was covered with trees, among the foliage of which the birds sang, and the lively squirrel gambolled and frisked, in the radiant sun, while the water foaming and tossing below, occasionally dashed the spray over the large masses of stone in its bed, like mimic waves.

It was with difficulty that I could tear myself away from this spot, but making my way forward and upward, for the stream could not be forded, I soon found myself on a projection which overlooked the fall, which threw itself over a rock some twenty feet in depth; but it is so placed, that I could not make a satisfactory picture of it, owing to my being on a level with the top of it, and not about thirty feet from it: this I very much regretted, because the surrounding scenery would have made a picture of especial beauty.

After exploring the stream for a considerable distance above the fall, and selecting such "bits" as particularly struck my fancy, I turned my face backwards, and arrived in the village just as the sun was gilding the top of the church spire.

(*To be continued.*)

Proceedings of Societies.

North London Photographic Association.

The usual meeting was held on the evening of Wednesday, April 24th, at Myddelton Hall; Mr. G. Shadbolt in the chair.

After the usual routine proceedings, the following new members were elected: Mr. Alexander, Liverpool; Major Burt, Nottingham; Mr. J. Harrison, Hull; Mr. E. Steegman, Nottingham; and Mr. Purnell.

Mr. T. A. Barber read a paper on "the Neutralization of the Nitrate of Silver Bath by Carbonated Alkalis," (see p. 209). After which he explained that one circumstance which had induced him to read this paper, was the fact that having formerly recommended the use of oxide of silver for neutralizing the bath, he had recently seen it stated by one of our photographic authorities, that it was a mistake to use oxide for such a purpose. He could not but think, however, that it was at once more scientific and simple, as it was only adding silver to the bath, whilst other methods added foreign matter in some shape.

Mr. Dawson entirely agreed with Mr. Barber as to the use of the oxide, than which he thought nothing was better for the purpose. He had tried both ammonia and carbonate of soda, but the bath soon got out of order. The oxide being insoluble in water was the only thing which ought to be used for the purpose, the nitric acid being neutralized by combining with the oxide of silver to form the nitrate, thus chemically speaking it was perfect, and practically speaking he had found it the best plan. With respect to Mr. Barber's remark on recrystallisation, he thought that by repeated recrystallization the organic matter was removed. He had tried it four or five times, and he always found the first crop of crystals to be purer than those which were subsequently obtained from the same solution. The "mother liquor" held the organic matter, but it need not be wasted, as it could subsequently be used for printing. Nitrate of potash could not, of course, be got rid of by recrystallizing; if it did not crystallize with the nitrate of silver, small crystals of it would get entangled with them, and it would be never entirely got rid of.

The Chairman said Mr. Barber's remarks applied chiefly to freeing the nitrate of silver from organic matter.

Mr. Barber said his remarks applied also to getting rid of the nitric acid. A good deal might be driven off by boiling.

Mr. Dawson had not found it difficult to buy good nitrate of silver, that which he had bought contained no adulteration but water and nitric acid. The best way to drive off the nitric acid when pure nitrate was desired was to pound down the crystals, and to keep them for a few hours in a shallow dish over a water bath. A solution made from crystals thus prepared would be found perfectly neutral. It was generally supposed that nitrate of silver could not be decomposed into nitrite except at a high temperature. One Saturday night he put some nitrate of silver, slightly acid, into a shallow basin in a water bath over a gas jet, and forgot it until the following Monday morning, when he found the nitrate of silver, which during that time could not have been at a higher temperature than that of boiling water, was decidedly alkaline, and in part converted into nitrite. This shewed that long-continued moderate heat—this was about 40 hours—would decompose the nitrate of silver, whilst a shorter exposure, such as five or six hours, produced no such decomposition. Every specimen of fused nitrate he had seen contained nitrite, and he did not think it was possible to fuse it without forming nitrite.

The Chairman observed that they had a visitor—Mr. Sutton, who he thought had been alluded to by Mr. Barber, who had thrown out a sort of challenge to him. Would Mr. Sutton take up the glove?

Mr. Sutton said he had been making many inquiries lately on the subject of nitrate of silver, owing to the prevalent complaints of its bad quality, and had obtained much interesting information. It appeared that the bulk of the nitrate of silver sold by different dealers was manufactured by one firm, by whom it was produced, not by the direct action of pure nitric acid on pure silver, but as a bye-product in the purification of gold. This metal, when it arrived in this country from Mexico, Australia, and other places, was first granulated, and then subjected to the action of strong nitric acid, which dissolved all the silver, forming nitrate of silver. The process of recrystallizing, as it was called by many firms, was nothing more or less than picking out the finest and largest-looking crystals, to sell at a higher price. If, however, the nitrate of silver obtained in this way were recrystallized, and the first crop of crystals were selected, they would be tolerably pure; and on evaporating and fusing the residue, instead of being clean and white, it would be found of a dirty tawny colour, particularly at the bottom of the evaporating dish. If this dark brown stuff were made into a nitrate bath, and the first crop were made into another, the results would be very different. The pure crystals would give rich, clean, vigorous negatives; the other, thin grey negatives, with veiled shadows, streaks, and all manner of abominations. If, then, a bath were made of the crystals, as at first obtained, before this separation had taken place, all the impurities would be present, and all the bad results, although perhaps in a slightly mitigated degree, would follow. The next question was, what were these impurities? Mr. John Williams and others had submitted this brown residue to a great heat, to carbonize any organic matter and get rid of it, but still something remained. Mr. Williams believed this to be a sulphate. He had added nitrate of baryta to the solution, and, although no cloudiness was produced, he had obtained a solid residue on evaporation, which he believed exhibited unmistakeable evidence of the presence of sulphur. Sulphuric acid was undoubtedly present in some samples of nitric acid; and if, in forming the nitrate of silver, silver were added in excess, when the nitric acid was exhausted, sulphate of silver might be formed. Mr. Williams, having carefully tested, had come to that conclusion. Assuming this to be true, the way to make pure nitrate of silver was to get pure granulated silver in the first place, and then to get pure nitric acid. To obtain the latter, any nitric acid might be taken, add to it nitrate of baryta, and then redistil it: dissolve in it the pure silver, and there was then obtained nitrate of silver as pure as it could be got. In recrystallizing this nitrate of silver they would not get colourless crystals, unless they added to the solution a very few drops of nitric acid, just sufficient to give very slight acidity. The first crop of crystals should be taken for a pure nitrate bath.

Mr. Barber thought that it might easily be tried if similar evil effects arose by adding a sulphur compound direct to the solution. He thought, however, the presence of organic matter alone was sufficient to account for the troubles complained of.

Mr. Dawson said a considerable source of trouble arose from the manufacture of silver direct from the oxide, or from the spongy silver reduced by means of zinc. This was an operation which could never be completely effected. He lately had about a pound of waste chloride of silver, which he reduced to spongy silver by adding zinc: after washing it he added rather an excess of sulphuric acid to remove the zinc. He evaporated the liquor, and then washed the precipitate until all trace of acidity disappeared. He then added nitric acid, and placed the solution in an evaporating dish, and kept it over a water-bath until it was a concentrated syrup, without crystallizing. He then made a solution, of about the strength of ninety grains to the ounce, for printing purposes; instead of a clear solution it was very turbid, which he could not account for, seeing that the syrup was perfectly clear. The filtrate from this he found to be chloride of silver. It arose from some of the chloride not being reduced by the zinc; and the chloride was not soluble in nitric acid. Spongy silver should not, therefore, be used for making nitrate of silver; it should always be fused, with a little lime and charcoal mixed with it, when it would form perfectly pure nitrate of silver.

Mr. Hughes had some years ago met with an exactly similar result. He had a quantity of chloride of silver, he had reduced it by the ordinary zinc method, and had then redissolved it in nitric acid, filtered it, and, on diluting it to a working strength, to his astonishment down fell a quantity of precipitate, showing that the chloride of silver was soluble in the strong nitrate of silver, but not in a weak solution.

Mr. Sutton suggested that it might be sulphate of silver which was precipitated.

The Chairman said it was well known that chloride of silver was, to a certain extent, soluble in a strong solution of nitrate of silver. There was one point to which Mr. Sutton had not alluded: Mr. Barber's paper appeared to him to be directed against some remarks made by Mr. Sutton to the effect that oxide of silver should not be used in neutralizing the bath.

Mr. Sutton said when oxide was added there was sure to be too much put into the bath; and then, to counteract that, too much nitric acid would be added, and so on, *ad infinitum*, whereas, when carbonate of soda was used in excess, carbonate of silver was thrown down, which had only to be filtered out, and the bath was neutral.

The Chairman observed that carbonic acid still remained.

Mr. Sutton said that he thought that was got rid of in filtration.

Mr. Dawson did not see any reason for adding an excess of oxide to the bath; it was insoluble in water, and it could be added in infinitesimal quantities.

Mr. Barber said a little oxide of silver was soluble in water.

Mr. Sutton added that the smallest excess would produce fogging.

Mr. Barber inquired whether Mr. Sutton considered it necessary to have his bath a little acid to make it work well, as he could not obtain satisfactory results with a perfectly neutral bath?

Mr. Sutton replied that with good collodion he could employ a neutral bath, but not with a cadmium collodion.

The Chairman said it was very easy to add a little free iodine to the collodion.

Mr. Sutton said it was notorious that a cadmium collodion could not be worked satisfactorily in a neutral bath when fresh iodized.

The Chairman had so used it.

Mr. G. Wharton Simpson said that Ponting's collodion, which was generally believed to be iodized with cadmium, was well known to improve by age, and the maker said it was better six months after iodizing than at first. Mr. T. R. Williams had recently informed him that some which he could not work when he first had it from Ponting, was in fine condition when he tried it twelve months afterwards.

Mr. Dawson asked if it were certain that Ponting's collodion contained a cadmium iodizer? The crystals obtained by evaporation when examined under a microscope were unlike those of cadmium.

The Chairman said that was scarcely a satisfactory test, as it was astonishing how different in form crystals would appear when contaminated with a little organic matter; their form was materially altered.

Mr Barber asked if good pictures could be obtained from a strictly neutral bath.

Mr. Dawson had obtained the best possible results so.

Mr. Simpson said when the bath was absolutely neutral every thing must be in the most perfect condition, as the presence of the smallest amount of foreign matter was sure to be indicated on the plate. The collodion must be good, and the manipulation careful.

The Chairman remarked, in reference to Mr. Sutton's statement regarding the presence of sulphur, that it would be foolish to say, in reference to any photographic experiment, that such and such a thing was impossible; still it seemed to him strong evidence against the presence of sulphur, that no cloudiness was formed on the addition of nitrate of baryta to the solution.

Mr. Dawson said the salts of barium were the most delicate tests for the presence of sulphuric acid, and that acid would not attack silver so long as there was an excess of nitric acid present.

Mr. Simpson said that Mr. Sutton had suggested that when there was silver in excess, and the nitric acid was exhausted, the sulphuric acid, if any were present, would begin to act upon the remaining silver.

The Chairman said even in that case the sulphuric acid would not attack the excess of pure silver: to do so it must be oxidized.

Mr. Sutton said boiling sulphuric acid might act in the silver, or the silver might have become oxidized by contact with the nitric acid. Mr. Williams had actually detected sulphur in combination with silver. That was a fact not to be explained away. It might be a sulphide or other sulphur compound; he did not insist on its being sulphate.

The Chairman said he could easily see the possibility of *sulphide* of silver being present.

Mr. Highley asked if Mr. Hardwich had not examined this question.

The Chairman said Mr. Hardwich had experimented as to the presence of organic matter only—not as to the presence of sulphur compounds.

Mr. Hughes said if the presence of sulphur had been discovered by analysis, it would be easy to prove the matter further by synthesis. The question might be easily decided by adding sulphur in some form to a nitrate bath, which ought to produce exactly the same results and appearances alluded to by Mr. Sutton, if his supposition were correct. That would be the complement to Mr. Williams's experiments, and would decide the question definitely, if any martyr to science would spoil his bath for that purpose.

Mr. Dawson then brought forward the table he had resently constructed for ascertaining the amount of nitrate of silver in a solution by means of its specific gravity, and proceeded to explain the precise and laborious steps he had deemed necessary for ensuring the utmost exactness. He had not trusted to the graduated measures usually supplied, but beginning with everything, *ab initio*, had graduated his own measures, the method used in effecting which he explained. Where he had used a standard salt solution, he had not relied either on the purity or dryness of the chloride of sodium, but had ascertained the exact strength by testing it with nitrate of silver made from pure silver dissolved in nitric acid, and ascertaining the amount thrown down by the salt solution. After forming the table by means of operations and calculations conducted on one method, he checked it by going over the whole again by a series of experiments conducted on a different method, and on doing so found that the table was exactly correct. He explained how the increase of the solution in *bulk* on the addition of silver entirely rendered any plan nugatory which was based on the measurement, first of the water, then adding silver, and ascertaining the specific gravity of the solution, as one ounce of distilled water and, say sixty grains of nitrate silver, would make more than one ounce of nitrate of silver solution; and the increase of bulk was not simply in the ratio of the addition of silver, but increased upwards. As regarded the value of the table, unless some one would go through it again they only had his word for it, but he could give them the fullest assurance that it was correct and reliable. (See p. 210.)

Mr. Hughes said that they could not separate without some very definite expression of the value of Mr. Dawson's labours; nor allow him to think that the great skill, untiring patience, and beautiful accuracy of his results went for nothing. Up to that moment no definite connection had ever been established between the specific gravity of distilled water, at 60° Fah., and that of solutions of nitrate of silver. All experiments showed how much depended on a knowledge of the exact proportions of that salt in their solutions; and Mr. Dawson had come forward to give them a new power. He (Mr. Hughes) should not have felt called upon to dwell upon this subject, but that Mr. Dawson, in his modesty, had not done himself justice, nor insisted with sufficient emphasis on the value and importance of his work. That table possessed an especial value, as proving a fact they might not have anticipated. The natural inference would have been that, having established the increase of weight and increase of volume for one proportion, it would stand the same for all strengths. But Mr. Dawson, having discovered a slight tendency to deviation, had pursued the examination, and they now had the exact statement of all strengths they would require to use, thus affording them a test of almost analytical accuracy, by the simple means of specific gravity. With such valuable results obtained, he could scarcely regret that he had, in the first instance, opened this discussion, although had he known all that was going to arise out of it he should scarcely have commenced it; still he could not but be gratified at the final results. Mr. Dawson had shown them now, and in his previous papers, how many and various the sources of error that beset such examinations, and that no mere rule-of-thumb method was of the slightest avail. That, instead of many of the methods in use giving even approximately correct results, the slightest deviation at any one point led them very wide of the mark indeed. The principle of estimating, by means of specific gravity, was shown to be correct; and if they were not content with the approximate results of the hydrometer, they could get absolute accuracy by means of the specific gravity bottle and this table.

After some further conversation on the relative value of Gay Lussac's method of estimating the quantity of silver and others, a vote of thanks was passed to Mr. Dawson, for the valuable information he had laid before them.

Various graduated measures, made by Mr. Dawson himself, and a very delicately-constructed pipette, graduated for every single minim up to 480 grains, which had been constructed for him by Messrs. Negretti and Zambra, together with a dropping-bottle, designed by Mr. Highley, were exhibited.

The Chairman announced that the Committee had been taking into consideration the propriety of altering the day of meeting from the last Wednesday in the month to the last Wednesday but one, so that they might get reports of their proceedings earlier than they did at present. He therefore gave notice that a motion would be made at their next meeting, which would be made special for the purpose.

The proceedings then terminated.

The American Photographical Society

The Society held its regular meeting for April, on Monday evening the 8th ult., in the Chapel of the University, New York; Vice-President Rutherford in the chair; John Johnson, Secretary *pro. tem.*

Harrison's New Lens.—The Vice-President, in reply to a question stated that the Committee on the new lens would probably be prepared to report at the next meeting. Mr. Harrison had been closely confined to his room by sickness for about six weeks. He had recently become convalescent, and was now preparing a very ingenious apparatus to be used in testing the lens. The apparatus is designed to overcome the difficulties in setting up an accurate drawing exactly perpendicular to the axis of the lens. The lens has been found on several occasions to be very useful in copying maps and paintings. Mr. W. H. Powell, the celebrated artist, has recently been commissioned by the Legislature of Ohio, to make an historical painting, commemorative of Perry's victory on Lake Erie. The preliminary sketch in charcoal has just been completed, and Mr. Powell was desirous of having a photographic copy produced. The sketch is twelve feet long and eight feet high. Application was made to several of our most skilful photographers, who, on examination of the case decided that it was impossible to make a copy unless the sketch could be removed from the studio to another room better lighted and longer. The attempt was about to be abandoned, when Mr. Harrison's lens was suggested, and the trial was perfectly satisfactory to all concerned; a good copy was made. The lens used has a focal length of twelve inches,* and stop of 4-10. The camera was placed sixteen feet from the sketch, and gave an image thirteen inches in length; the same lens would have taken in the whole view within twelve or fourteen feet, but would have made a copy larger than was desirable. (The Vice-President exhibited a print from the negative, which was passed among the members, but no one was able to discover distortion, deficiency of sharpness, or unevenness of lighting.)

Mr. Seely presented views of the exterior and interior of Mr. Anthony's store, made by one of the new lenses, and remarked that he was well satisfied of the great merits of the lens.

Mr. De Rahm presented a view of his studio made by the lens.

Printing and Toning.—Mr. Snelling then read a paper on the practical details of printing and toning.

Mr. Campbell.—Do you consider prints permanent which are made by your processes?

Mr. Snelling.—I have prints made five or six years which are not faded. My experience leads me to believe that prints toned in the acid bath are most permanent.

Photographic Notes and Queries.

Modification of the Fothergill Process.

Sir,—The albumenate of silver process being likely to have a pretty extensive trial, the following remarks may be of a little service to your non-chemical readers. It appears not indispensably necessary to have a "Fothergill collodion" for this modification. Always commence development with a minimum quantity of silver in the developer—a flat 12 or 16 oz. bottle laid in a porcelain tray makes an excellent developing stand. The formulæ I have succeeded with are in principle the same as mentioned by Mr. Hannaford, but my albumen is more dilute, and runs through the filter readily; it is made of

Albumen	1 oz.
Water	3 ozs.
Strongest ammonia	24 drops.

Shake, and when required for use add to every ounce 6 drachms of a 5-grain solution of nitrate of silver, shake and filter. Develop at this season with 1½ grain pyrogallic to the ounce, and 15 minims glacial acetic acid and silver solution, more or less, according to exposure.—I am, sir, yours, &c.,

Wm. Bartholomew.

Fareham, April 27, 1861.

Dear Sir,—In reference to Mr. Hannaford's modification of the washed albumen process (with all due respect for that gentleman), it does not obviate the markings and stains under the same circumstances upon the plates. Having just concluded my comparative experiments, which have extended over twelve months, I find them to arise from four causes:—1st, unsuitable collodion; 2nd, imperfect washing; 3rd, draining the plate; 4th, drying the plate.

If any benefit to your readers I will give my method in detail, the whys and wherefores, from the laboratory to the field, and bring them back with two good acquisitions—good pictures, good appetites.—Yours, &c. H. R. Nichols.

2, *St. Jude Street, April* 27, 1861.

[We have just received our correspondent s details of his method, which we will publish next week.—Ed.]

Yellow Glass for Dark Rooms.—Dissolve one ounce of shellac, one drachm of gum elemi, and one and a half ounce of powdered gamboge, in six ounces of vegetable naphtha; when the gums are quite dissolved, which will be in a day or two, decant the varnish off the dregs, and apply to the glass—quite dry, and rather warmed—with a broad camel-hair tool. It will be dry in a few minutes, and may then have another coat, or more, if requisite, to give the desired tint. The glass transmits a good softened yellow light, quite non-actinic. There is also the advantage that the varnish can easily be applied to existing windows, lanterns, &c., if desirable.

* From the back lens we presume.—Ed. P. N.

Talk in the Studio.

THE ECLIPSE PHOTOGRAPHS.—At a recent meeting of the Astronomical Society, Mr. DE LA RUE gave an account of the progress made in the preparation of tho photographs of the eclipse taken in Spain. He said it had been found necessary to enlarge them, and that hitherto the weather had been so unpropitious that, although he had spent twenty-one days by the side of the camera, no good result had been arrived at. He exhibited three photographs to show the sort of development obtained, and from an inspection of these, we think great things may be expected.

EXPLOSION OF GUN COTTON.—*Humphrey's Journal* records a serious explosion on the premises of one of the contributors to that journal. It states that :—"On the morning of Friday, the 29th of March, at about 9 o'clock, the numerous denizens of the vicinity were startled by the report of a most fearful explosion. Crowds of people soon rushed into the building, where a scene of destruction met their astonished vision. Many of the largo panes of glass in the front windows were blown clear across Canal Street. The three windows in the rear, where the laboratory is situated, were nearly demolished, and the whole of both sashes in the window farthest from the furnace, where the explosion took place, were blown into splinters. The glass partitions were all scattered into inch-pieces, and it is a great wonder that the building was not set on fire. Mr. Dornbach was standing in the centre of the room at the time of the explosion, and, wonderful to relate, escaped comparatively unhurt. On a sand bath over a hot fire was placed, in a large wooden box, upwards of ten pounds of gun-cotton in process of drying, when suddenly the whole exploded as if it had been a keg of gunpowder. Mr. D. says the room was filled with flame, which forced its way through the cracks and crevices of the board ceiling into the room above, scaring the inmates not a little; they thought the building was all in a blaze, but the woodwork was merely scorched. The brick wall was started by the explosion, The most singular part of it is, that a glass flask holding nearly a gallon of ether in process of being concentrated, and standing on a frail support directly over the cotton, was not disturbed in the least.

NEGATIVES WITHOUT A SILVER BATH.—A correspondent informs us that he has some specimens taken two years ago without a nitrato of silver bath, by a process similar to that referred to by Mr. Bellini; wo believe we shall have further particulars in our next.

PHOTOGRAPHIC SOCIETY OF SWANSEA.—Our esteemed correspondent, Mr. Jones of Swansea, is endeavouring to form a Photograbhic Society at Swansea. Mr. Llewellyn, well known as amongst the earliest successful photographic experimentalists, has consented to act as president. We commend the subject to the attention of our readers in the Principality, who we hope will not allow such a project to fail.

A NEW COLLODION.—A new field for experiment has recently been opened by Mr. Joseph Dixon, of Jersey City. Accident had thrown in his way a small quantity of the white fibrous substance found in the pod of the plant commonly kuown as the Milk-weed (*Asclepias*). The enquiry naturally arose whether this substance could be substituted for common cotton wool, in the manufacture of collodion. It was immediately subjected to the usual nitro-sulphuric acid treatment, and the substance produced was found to be highly inflammable and under the proper manipulation would undoubtedly have all the explosive qualities belonging to ordinary gun-cotton. The milk-weed fibre seems however to comport itself more like wool and similar animal substances, and undergoes a chango of colour from a pure glossy white to a dark yellow, indicating doubtless the presence of nitrogen in its composition. It dissolves as readily in ether and alcohol as the common gun-cotton. Mr. Dixon confidently expresses the opinion that this new substance possesses peculiar advantages, but a number of experiments are required to ascertain its behaviour under all conditions, and to definitely fix its value as a photographic agent. He has sent for another supply of the raw material, and hopes to report fully in relation to it at the next meeting of the society.—*American Photographic Journal.*

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, PATERNOSTER-ROW.

To Correspondents.

W. W.—We are glad you found our suggestion meet yout difficulty. 2. In copying anything with polished or varnished surface, such as daguerreotypes, glass positives, or oil paintings, it is necessary to place them in such a positiou that no reflected light is throwu from its surface iuto the camera. The best method of avoiding this will be decided by the position of your light; but two or three experiments will euable you to determine the position.

A. X.—The cause of the marks on your tannin plate is imperfect washing before applying the tanuiu. 2. The want of intensity iu a taunin negative is a new complaint, the cause of which we cannot tell. All we have tried and seen, have had a tendency to over intensity. 3 The length of exposure will be determined by the lens and stop as well as the light. At least six or eight times as long as for a wet plate. 4 We cannot tell from your description the cause of the spots in your friend's paper negatives. 5 Half an hour or less is loug enough for the prints to remain in water before toning. 6 Yes, but the results will not be so certainly good.

Y. H. B.—Success in instantaneous photography simply demands that collodion, silver bath, and developer, be in the best condition for sensitiveness, that a good lens be used, and a good light selected. A good bromo-iodized collodion, excited in nitrate batb made from *pure* nitrate of silver, nearly neutral, and iron developer are the best chemical aids. The light must be good, and the lens must not be of a very long focus, uor used with too small a stop. Small pictures are most easily mauaged in instantaneous work.

SMOOTHFACE.—You will find a rolling-press advertised by Mr. Francis in our advertising columns.

HENRY H.—Your negative arrived smashed to a thousand pieces, not one of which was half an inch square. From your description of your difficulties they appear chiefly to arise from the collodion. A cadmium collodion often gives the inequalities of film of which you complain, and unless the bath contain acetate of silver, it is uot always easy to obtain intensity. From what we can see of the fragments of your negative which arrived, it was considerably over-exposed. Try another collodion, giving more density, or add a little acetate of silver to your bath The latter is a plan we never adopt ourselves, however. Use a little more silver with your developer. Do not use a whole plate portrait lens for landscape work without a stop.

G. C. G.—The formula for alabastrine solution is, as we stated last week, a trade secret. There are various modes of producing a similar result. A solution of bichloride of mercury whitens a glass positive, but the tendency is to give a cold bluish tone, whilst the alabastrine solutiou announced by Messrs. Squire and Co., is intended to give a pure blue.

G. C.—Your pictures are scarcely up to the mark yet for exchange with the members of the Stereo Exchange Club. Nos. 1, 2, and 3 are all a little under-exposed. No. 4 is better in this respect, but all the pictures are wanting in sharpness, whether it be the fault of your lens or bad focussing we cannot say. The subjects of your pictures, although probably interesting to yourself from association, have not much value as pictures, and would not, on that account, be acceptable for exchange. You will learn after a little more practice to descriminate better what objects are worthy of selection for their picturesque qualities. The splitting and curling off of the film arises either from bad collodion or imperfectly cleaned plates. We shall be glad to hear of your further progress.

HENRI BELLINI.—Your lengthy communication arrived too late for attention this week. It shall receive our best consideration in our next. We fear it is too long for insertion in its entirety.

C. C. Belgium.—We will write to you privately.

J. L. F.—Your negative is much under-exposed. Double the exposure would probably give you a good picture.

SAMUEL ARTIDGE.—We are obliged by your communication, which shall receive attention in an early number.

SWANSEA.—We are not in possession of further details ou the method of colouring, beyond those given in the paragraph to which you refer. The water glass is a solution of silicate of soda; in what manner it was employed in colouring photographs we do not know. In order to get water colours to take kindly to the surface of albumenized paper, the photograph should be treated with a preparation for the purpose, or a little ox gall mixed with the colour. So far as we can see by examination, the paper you forward may be used for photographic purposes. You need not hesitate to write to us, we shall always have pleasure in hearing from you.

T. K.—The best toning bath is that of alkaline chloride of gold, and it is therefore the cheapest. Chloride of gold 1 grain, bicarbonate of soda 5 grains, water 10 ounces, will tone about 8 whole plate pictures. The gold costs twopence per grain. 2. Add bromide of ammonium in the proportion of about half a grain to each ounce of collodion, aud you may then use it for positives. 3. Toning with platinum is not so efficient or so cheap as toning with gold 4. Hughes' dead black varnish is one of the best we know for backing positives. The price of the vols. of the PHOTOGRAPHIC NEWS which are now in print is 10s. 6d. each

H. B. Y.—To make a good positive collodion, take pyroxyline (not made at a very high temperature) 4 grains; alcohol S. G. 820, 4 drachms; ether 4 drachms, iodide of cadmium 2 grains, iodide of ammonium 2 grains, and bromide of ammonium half-a-grain. 2. Any quiet neutral colour wil do for the interior of a glass room. A drab or dove-colour answers well. The last edition of Mr. Hardwich's Chemistry is the sixth, and is only just out. It is not likely that a seventh edition will be published within a year or two we should think.

Y. A.—Your long letter of enquiries arrived too late for answer iu the present number. It shall receive attention in our next.

X. X.—There are letters awaiting an advertiser who gave this signature last week.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the NEWS giving the exact reference. Letters intended for the EDITOR should be addressed expressly to him.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 140.—*May* 10, 1861.

PHOTOGRAPHY, AND THE INTERNATIONAL EXHIBITION OF 1862.

The photographic community at large were somewhat startled when, some weeks ago, the first rough draft of the classification proposed for adoption in connection with the coming International Exhibition was published, in which photography was placed under the head "machinery," and in the, doubtless highly respectable, company of "ship's tackle," "agricultural implements," &c. Our own first impression of the matter was that it was purely an inadvertency or oversight. It appeared too rich a joke to suppose that the pictures of such men as Bedford and Mudd, Wilson and Fenton, Lyte and Heath, Rejlander and Robinson, Williams, Claudet, and Mayall, and a host of others, could seriously be regarded as rightly classified amongst railway plant, machinery, and tools; and the more so, when we remembered that the royal family of this country were amongst the warmest admirers and patrons of our art.

Knowing, however, that the surest way to render permanent the blunder was to enlist the *amour propre* of its perpetrators in its defence, by a public condemnation of it, and perceiving no readier means of calling the attention of the authorities to its rectification, we resolved to write to Her Majesty's Commissioners, pointing out the error, and the evil influence it must have in preventing a fair representation of our art. Accordingly, a little more than a month ago we forwarded a letter, of which the following is a copy:—

"*April* 11, 1861.

"*To Her Majesty's Commissioners for the Exhibition of* 1862.

"Gentlemen,—Referring to the proposed classification of articles for the International Exhibition next year, will you permit me, as being familiar, from my position, with the views and feelings of the mass of British photographers, amateur and professional, and as, in a non-official sense, representing them, to point out, respectfully, the injustice to them and the art which is involved in placing photography under the classification 'machinery and engineering.'

"It has been the aim, for some time past, of photographers to render their art worthy of consideration amongst the fine arts, and has of late, in portraiture, landscape, and re-productions of paintings, &c., been adjudged by connoisseurs worthy of such consideration. And notwithstanding its importance in connection with engineering, &c., a very large class of the finest photographic productions could not, with propriety, find admission into a class designed for machinery.

"May I respectfully suggest, gentlemen, if the matter be not definitively settled, that photographs be admitted into the department designed for works of Fine Art, and that they may be so classified in any future announcements, as otherwise I fear that many valuable productions of the art will be kept out of the Exhibition.—I am, gentleman, your humble servant, G. Wharton Simpson,

"*Editor of the* Photographic News."

In due course we received the following reply:—

"International Exhibition. 1862.

"Offices, 554, *West Strand London, W.C.*

"16*th April*, 1861.

"Sir,—I have the honour to acknowledge the receipt of your letter of the 13th inst., which will be laid before Her Majesty's Commissioners in due course.—I am, sir, your obedient servant, F. R. Sandford, *Secretary.*

"*G. W. Simpson, Esq.*"

What further attention our suggestion received we are not in a position to state; but as we are not at present aware that any other communication was made to the Commissioners, we may fairly assume that it had some influence in the steps which followed, and which we hope may issue in a satisfactory arrangement, in which the claims of photography shall receive proper acknowledgment.

From an announcement made by the secretary of the Photographic Society on Tuesday night, we learn that a communication from the Commissioners had been addressed a few days ago to the Chief Baron, as President of the Society, suggesting that six or eight persons should be appointed to advise with the Commissioners as to the proper steps to be taken in connection with the representation of photography. A meeting of the council was at once called, when it was very properly resolved that no steps should be taken until photography should be placed in a proper position; classification amongst the works of fine art being claimed as its proper place. The Chief Baron, we understand, then wrote a letter of remonstrance to the Commissioners, arguing the case very pointedly, and conveying the resolution of the Council of the Society. So far as our information goes, the matter thus remains; but we cannot but hope that a wrong so palpable and indefensible, only requires to be pointed out, and the remedy firmly claimed, to receive a satisfactory solution.

We are glad to record that the steps of the council of the society were so prompt and consistent with the dignity of art, when once their attention was aroused by the communication of the Commissioners; although we should have been better pleased to have been able to state that they had taken the initiative in a matter so important, and in which they alone could act with that weight and influence the occasion demanded.

We may here remark that the publication of the official list of the classification intended, whilst it removes the idea that any mistake had been committed in the first published list, still leaves the matter in a somewhat ambiguous state. In Section II., Class 13, we find "Philosophical Instruments, and *Processes* depending upon their use;" and immediately following, Class 14, "Photographic Apparatus and *Photography*," not *Photographs*. From this allocation it would seem that photography as a *process*, and not photographs as works of art, is referred to. Without material alteration in the classification, it is only necessary, therefore, to add "Photographs," to the fourth section—"Modern Fine Arts," to render the classification satisfactory and complete. And as the Attorney-General, in his new Copyright Bill, has essentially defined photographs as "pictures" and works of fine art, Her Majesty's Commissioners can scarcely have much difficulty in following so righteous an example. Now, however, is the time for vigorous remonstrance; and we recommend to the various photographic societies throughout the kingdom, to take consentaneous action, and memorialize the Commissioners, so as to assist the parent society in impressing upon them the extent of the wrong, and the amount of indignation it has excited.

THE TANNIN PROCESS.

It is important that the real grounds of merit in this valuable process should be well understood. It is not a quick process. It is simple in manipulation; and under fair conditions, clean, brilliant, and certain in results,—the negatives having all the qualities which give rich vigorous prints. The difficulty which has troubled many—the tendency of the film to leave the plate—is, we are convinced, to be met without complicating the formula by the coating of gelatine. The use of a moderately adherent collodion, and, more especially, care and skill in the manipulations, will prevent the frequent loss of films. In our own operations with stereoscopic plates, we have found that the whole question of results in this respect was decided by caution or carelessness. We have recently seen a number of negatives by this process, on plates nine inches by seven, taken by Mr. Sutton, in Jersey, in which all the films were perfect, and no difficulty had been found in preserving the result. The chief evil to be guarded against, then, is under-exposure. This has been the fault of most of the negatives we have seen. Those to which we have just referred, although clean, rich, dense, and brilliant, are deficient to our taste, in softness and detail. They appear somewhat under-exposed; notwithstanding that some of them were, we understand, exposed fifteen minutes. We must not be understood, however, as speaking of this as necessarily an evil. If a process be not very rapid, it happens under many circumstances that the next best quality it can possess is to be very slow, as many landscape photographers are well aware. In the tannin process it should be remembered that it is scarcely possible, within reasonable limits, to over-expose, and that full exposure only will give softness and harmony to the negative.

Amongst the very finest results we have seen by this process are some stereoscopic pictures by Mr. Penny of Cheltenham, some of his prints we have seen reminding us much of Mr. Mudd's pictures; in saying this we are according the highest praise we can express. We wrote to Mr. Penny for a few particulars of his manipulation, exposure, and general experience in the process (especially referring to one gem we had seen). We shall here subjoin some extracts from his courteous reply. He says:—

"It will afford me pleasure to give you all the information I can about my working of the tannin process.

"Not having taken it up in an experimental way, my practice has hardly been exact enough to warrant my drawing from it any very certain general conclusions.

"I am, however, able to furnish you with the necessary information about the particular picture referred to. The negative was prepared with Ponting's collodion, excited in a very old bath rather acid, of nearly 40 gr. to oz., thoroughly washed, and tannin solution 15 gr. to oz., floated over it. Exposed early in March, about 9 A.M., in clear sunshine for 5 minutes, developed with pyro $1\frac{1}{2}$ gr. to oz., a small quantity of citro-nitrate being added, cleared with cyanide.

"One 9 by 7 plate I took with a 14in. slow landscape lens, $\frac{1}{2}$in. stop, in 20 minutes, with a very bright light; it turned out all one could desire; but, the fellow prepared in all respects the same, being exposed 5 weeks after preparation, in a *weak* light for half-an-hour, was wooley and wanting in vigour, with transparent sky, &c.; another plate, prepared only 24 hours before exposure, and exposed under the same circumstances of light, gave a similar result, from which I judge the process is not suited for long focus lenses, except with a clear strong light.

"I always expose long enough to get the deepest shadows impressed, otherwise there is danger of getting the picture hard and intense: the light being good there seems little fear of over-exposure.

"A photographic friend and companion of mine, a very careful manipulator, complains of this tendency, if ever so much exposed; mine, on the contrary, have of late been rather too transparent in the skies when fully exposed. It seems that the difference of collodion will account for the different results.

"I have been using lately a collodion of which I can only say, that it is a mixture of remnants both negative and positive, some of them very old; it contains bromide, and is rather alcoholic.

"The film sometimes swells and rises from the plate under development; and I have now and then as a consequence lost a picture from it splitting up when dry. The negatives by this process, in my experience, lose more in fixing, whether by cyanide or hypo, and in varnishing, than any other.

"While experimenting lately upon Fothergill modifications, for which my old collodion mixture seems suitable, it occurred to me to try whether one could safely apply tannin upon a well washed albumen plate, and if so, whether it would not be beneficial by hastening and keeping clean the development of the plate. Also, whether the albumen over the collodion would fix the film, as it does in Fothergill, and so counteract the loosening effects of the tannin.

"The plate was prepared in the following way:—After sensitizing, it was washed in a bath of distilled water, which had been used for some time for washing plates in, and therefore contained a small quantity of nitrate albumen, 1 part to 3 of water was poured over it; after washing thoroughly, the tannin solution was floated over.

"No staining being seen, I exposed the following morning for 6 minutes in bright sunshine.

"It developed certainly cleaner and quicker than ordinary Fothergill; but the film rose on the thicker end, and showed symptoms of cracking on drying. I detail this first experiment, that others may follow it up if so inclined; the specimen is sent for your opinion.

"The negatives were all taken with landscape lenses $4\frac{3}{4}$in. focus $\frac{5}{16}$ diaphragm.

"No 1 is a sample of extreme exposure. No. 2 is from the new hybrid preservative."

The sample of extreme exposure forwarded, is a stereoscopic print, the plate described as exposed at eight o'clock on an April morning, in brilliant sunshine, for twelve minutes, with, we presume, lens and stop described. It is possibly very slightly over-exposed; but is nevertheless a charmingly harmonious print, without the slightest chalkiness, certainly; but still far from being a weak picture. The sky prints through, giving a pleasant atmospheric tint. The highest light are the small reflections on the surface of a pool of water, which being in immediate contiguity to deep shadow of an overhanging bank, which is the darkest part of the photograph, at once gives brilliancy to the whole picture.

The print from the albumino-tannin plate which was exposed eight minutes under the same circumstances as the other, is also a soft harmonious print, but is less brilliant, and shows more signs of over-exposure than the other. The cleanness and rapidity of development described by Mr. Penny give the albumino-tannin process claim to further trial.

PHOTOGRAPHY WITHOUT THE NITRATE BATH AND WITHOUT DEVELOPMENT.

We have received from Mr. H. Bellini a very long communication in reference to some remarks we published a fortnight ago under the above heading. These remarks, Mr. Bellini thinks, are calculated to injure him in his business, and to damage his reputation for veracity, and proceeds to explain the miscarriages which occurred when we called on him six months ago. As these explanations would occupy about a couple of our columns, we should not feel justified in devoting so much of the space belonging to our readers to matters so purely personal. We will, however, without entering into any discussion of the matter, meet the case, so far as Mr. Bellini's feelings are concerned, by assuming that his explanations are quite satisfactory, so far as the occasions to which we referred are concerned. But we must remind him that these miscarriages having occurred, he has taken no steps since, although upwards of half a year has elapsed, to verify the statements in his first letter which we published, and that, therefore, if Captain Dixon or anyone else in the meantime patent any similar discovery, Mr. Bellini has, as we before stated, only himself to blame. So far as we can see, the claims made by Mr. Bellini and by Captain Dixon are in many respects essentially different, and whilst they do not necessarily clash, if the former be justified by practice, the latter would be entirely swallowed up, unless it presented other points of superiority, which results can alone determine.

After making the explanations referred to, Mr. Bellini proceeds to detail the various experiments made in working out his idea. As they show much ingenuity, and traverse a comparatively untrodden field, they will, we think, although somewhat lengthy, prove interesting to our readers. We shall, therefore, although in some of his assumptions we think he is scarcely exact in his chemistry, give them as as they stand. After his personal explanations he proceeds:—

"As I do not wish, and. indeed, never entertained the remotest idea of 'misleading' any one who might place trust and confidence in my statements, I will endeavour as briefly as possible to explain my theory—which is simple enough in practice—together with the method by which I at last carried it out, I contend very successfully, notwithstanding it involves new principles in chemistry hitherto unknown, or but little understood.

"Firstly.—Inasmuch as it is generally supposed, that all substances capable of developing a latent image (by continuing the precipitation of metallic silver, already commenced by the action of light) have also tho property of precipitating silver from all solutions of its soluble salts; that this is not tho caso under certain circumstances I will most distinctly prove.

"Secondly.—That the 'lactate,' or 'milk of silver,' and also the 'chlorato' of silver, are vastly superior to the ordinary nitrate, as these salts yield a much more sensitive surface, and in solution they are not liable to change.

"Thirdly.—That a plato can even be coated and sensitized in the ordinary way, and immediately before exposure may be washed quickly with a very weak pyrogallic, or pyrogallic and silver solution, which will not only render the plate highly sensitive to light, but also cause a partial development of the latent image as soon as tho light begins to act, consequently, upon its removal from the dark slide (in the dark room), it is nearly developed; a picture taken in this way, with a good mixed collodion of a reddish colour, will give most startling life-like pictures, with a very pretty red-lavender background.

"(Commence with a quarter of a grain of pyro acid to the ounce of distilled water.)

"Fourthly.—That it is quite possiblo to combine collodion, silver, and an iron developing solution in one yellow glass bottle, without precipitation taking place, (and yet each shall answer the same purposes as when used separately) providing always that the quantity and quality of the chemicals used are strictly attended to; in this alone lies tho grand secret—the Eureka of photography.

"Fifthly.—That 'white twisted shellac,' with or without the addition of 'gum sandarach,' and prepared in the same way as 'gun-cotton,' can be used to hold the bromide and iodide of silver, for forming a sensitive medium on glass.

"It has long been well known to *savans* and continental chemists that certain silicates, starch, gums, &c., &c., are acted upon in a very pecular manner by different acids, which dissolve them into a thick mucilaginous liquid, precipitated by water, and very soluble in alcohol and sulphuric ether. Shellac prepared in the same way as 'zyloidin' forms a beautiful hard and colourless white varnish. I may here observe, that when some of the silicates and silver sand aro thus treated with different acids, you have the key to the manufacture of 'liquid glass.'

"The idea having frequently occurred to me, that it might be possible to incorporate the sensitivo bath with the collodion, I determined to make a few trials for the following reasons; namely. very few samples of alcohol are pure, or what is called 'absolute' or 'anhydrous,' consequently there is generally sufficient water in an ounce to dissolve from 30 to 60 grains of nitrate of silver in the course of forty-eight hours, and thus absord all the water, leaving the spirit perfectly pure: we will, for the purposes of argument assume that 30 grains is the utmost quantity of silver an ounce of alcohol will dissolve (the tbe usual working strength of a silver bath); we now proceed iodize it, according to fancy, with any of the soluble salts, I prefer the iodide and bromide of silver, which I myself specially prepare for this purpose, the usual quantity to the ounce, this being again dissolved you will obtain a very sensitive fluid, of a bright yellow colour, with the nitrate of silver in excess of the iodide, this is, of course, absolutely necessary.

"Now we want the developing agent, and I add, very cautiously and gradually, for that purpose, a few drops of a tincture of iodide of iron, till the proper result is obtained, and which renders it so extremely sensitive to light that the action is almost instantaneous, a portion of protonitrate of iron being thus formed within the film itself, it now requres to bo briskly shaken for ten minutes, and then allowed to settle for twenty-four hours beforo use, it must also particularly bo kept in a stoppered yellow glass bottle.

"Supposing it now to be ready for use, we proceed to coat a plate and expose it in the camera, on its removal from the dark slide, in the dark room, and on holding it up to the yellow, or red glass light for a few seconds, we perceive that the latent image is gradually but surely developing itself, in fact, it must either be placed next in water, or a weak solution of cyanide of potassium to stop this most extraordinory self-development. and afterwards finally washed and allowed to dry spontanoously in a vertical position, with the film side to the wall.

"If tho fluid is 'curdy,'—which is never tho case, unless water is present—(this is generally the case when insufficient silver has been added to absorb all the water), filtering in the dark through a double piece of white silk, and tho addition of more silver are the only remedies I am acquainted with, that will effectually clear the preparation and render it fit for use.

"I have also tried tho addition of a minute proportion of pure white pyrogallic acid to tho above (omitting the iodide of iron), with the view of forming a sort of 'tannato of silver' in the film; but on the plate being exposed in tho camera, a very curious phenomenon ensued. The image turned of slaty-violet hue, and on trying to render the latent image apparent by forcing it with an ordinary developing solution, it turned an opaque deep black. (The exposure too was rather long).

"These were, you must most distinctly understand, only a few of my first attempts to achievo the end I had in view; and my partial success induced me to make fresh trials with other materials, but I sadly felt tho want of some friendly practical chemist's advice, or the opinion of some master mind at different stages of my experiments; but the fear of failure, and the ridicule which I knew, from bitter experience, would be inevitably attendant thereon, deterred me from seeking any, save what I could glean from reading all the best works on chemistry. I feel convinced, that if I had received a little assistance of the above description (my natural intuitiveness of perception having already solved the problem), the public would have been working tho invention long ero this.

"It seemed, from the appearanco of the plates, to want only a very little something; but bearing in mind the good old proverb that 'patience and perseveranco frequently overcome the greatest difficulties,' I essayed a final attempt with totally different materials, which in the end proved successful.

"I next dissolved half-an-ounce of the best white twisted shellac and a quarter of an ounco of gum sandarach, in one ounce and a half of pure alcohol, and proceeded as before—the result was a veiled and rather indistinct picture, spoiled, without doubt by a hard, horny, cellular, network film, which, while it formed a coherent film on tho glass, and stood admirably the effects of a strong solution of cyanide of potassium, had nevertheless a very harsh and unpleasant appearance—a common developer even being unable to penetrate the hard film. I, notwithstanding this very great drawback, felt elated and encouraged to proceed.

"I next treated tho white twisted shellac in the same way as 'zyloidin,' and gun-cotton with nitric, and nitric and sulphuric acids, soaking it afterwards well in distilled water, then again in ditto with a little ammonia in it, and finally well washing. It had now a white, soft, waxy, mucilaginous, parchementy appearance (it was of course explosive when dry).

"When I judged the water was all absorbed by the dryness of the atmosphere from tho shellac, I added half-an-ounce of it to one ounce of pure alcohol (omitting the gum sandarach), I tried sensitizing this with every description of the salts of silver, but succeeded best with the 'chlorate' and 'lactate,' or 'milk of silver' prepared by myself specially for this purpose. I have also sometimes found it beneficial to render the solution at times slightly acid or sour with glacial acetic acid, or lemon-juice. The ether is added in tho usual proportions.

"Having iodized it with any of the usual salts (iodide and bromide of silver are best), and also tested it to see whether it will yield a picture with an ordinary developer—you next proceed to add the developer slowly.

"The Developing Agent.—Tincture of pure iodide of iron must only be added very gradually after the other ingredients are all dissolved, shaking the bottle well and trying a plate between the addition of every few drops until you have ascertained pretty nearly the quantity it will be necessary in future to add.

"Note.—The exposure, and action of the light on these very sensitive plates is almost instantaneous; but the latent image is not visible for a few seconds afterwards.

"The iodized collodion film, thus prepared being much superior to a collodion film, more 'pre-sensitive' and tenacious, independent of the astonishing delicacy and the extreme minuteness of the general detail, combined with great solidity, purity of the whites, and blacks, &c.

"I superimposed a negative on one of these plates (which I know will remain moist and sensitive for a long time), and it gave a fair print.

One very great object is attained by the use of my collodion, namely, that you can prepare the day before you intend to 'fire them off' as many of these plates as you may think proper; they will keep moist and retain their sensitiveness if preserved carefully from the light; this surely is worth our best attention.

"I shall have it ready for sale next month; all I ask is a fair field and no favour, and that you will not condemn or prejudge a long stride in the right direction in consequence of a partial failure, over which I certainly had but small control.

I was perhaps somewhat premature in making the announcement so soon, or till the preparation was ready for immediate use, but I wished the extraordinary fact to be published, partly to secure my just claim to being the sole inventor of the process ('mind being property, as well as matter,' in my opinion), and I also wished as soon as possible to lessen the labour and time usually occupied in rendering the glass plate sensitive.

"Shellac dissolved in spirits of wine, has been used also to preserve the stone, and prevent the further decay of the Houses of Parliament, and the result proves that it was admirably successful, where protected from rain.

"Acting on a hint given by a very clever friend of mine, that 'turmeric' could be employed to increase the density of all negative collodions, I have found that a drop or two of a filtered and very weak 'tincture of turmeric' added carefully, will in truth produce any required degree of intensity, the lights being in that best of all conditions, semi-transparent, thus yielding clear, round, soft, and very solid prints.

"Apologizing for the necessary length of this reply, and the detailed instructions.—I am, sir, very respectfully yours,

"Henry Bellini."

We once more repeat that Mr. Bellini's position is a very simple one. He has merely to verify his statements by practical results, and he may depend upon it that honour and profit await him, and he will not, we think, have anything to fear in the shape of injustice from any part of the photographic press. In regard to his latter remark as to turmeric, he may possibly not be aware that it was proposed for the purpose indicated sometime ago by Dr. Mann Sanders.

In another column will be found a letter from Mr. Smith, of Bath, detailing some experiments in a similar direction. M. Poitevin published a process last summer in which nitrate of silver was added to collodion, but excited subsequently by pouring over the film a solution of iodide of potassium. The details will be found in our third volume and in Photographic News Almanac.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulteration, and Analysis.

Chloride of Silver is decomposed by a great variety of agents; of these the chemical action of light is one which is most familiar, although this kind of decomposition, by this agent is apparently enjoyed only by the chloride which is prepared in the wet way (i.e. by double decomposition between silver solution and a soluble chloride). Some curious experiments have been recorded on this subject by Dr. Percy. This chemist has shown that when chloride of silver has been prepared by the direct union of metallic silver and chlorine gas, it undergoes no darkening whatever, even when fully exposed to sunlight, a specimen having been kept for some months fully exposed to light in common air without any darkening whatever taking place. The decomposing power of light on the ordinary precipitated chloride of silver is likewise capable of being modified in several ways. Amongst the most remarkable may be mentioned the following instance which is likewise due to the experimental skill of Dr. Percy. Some chloride of silver was placed in a small glass tube, chlorine gas was then introduced, and the tube closed. When the instrument was exposed to the light a certain degree of darkening took place within a given time; and when removed to the dark the chloride of silver assumed its original whiteness, gaining at the same time its sensitiveness to light. The above experiments point to a radical difference in the molecular constitution of chloride of silver prepared in different manners, for whereas chloride of silver prepared by the direct combination of its elements refuses to darken in the sunshine even when in the ordinary atmosphere the precipitated chloride is darkened when surrounded by chlorine. The last mentioned property of chloride of silver was suggested by Dr. Percy as a ready means of making an instrument for measuring the amount of chemical energy present in light. A series of tubes were to be arranged side by side. These being each charged with chloride of silver and sealed up containing an atmosphere of chlorine were to be exposed to the light each for a different number of minutes. Upon examining which tube had darkened to a certain standard degree of darkness, the negative photographic value of the light could be at once seen. Amongst the other decompositions of chloride of silver which may interest the photographer may be mentioned the following: alkaline sulphates in solution readily reduce it when freshly precipitated to the metallic state on boiling; the resulting metal may be obtained quite pure by washing it in ammonia. The following metals, especially in the presence of a little free acid, and aided by heat, reduce it to the metallic state:—Arsenic, antimony, bismuth, zinc, cadmium, tin, lead, iron, copper, and mercury. A solution of caustic potassa of a specific gravity of not less than 1·25 decomposes recently precipitated chloride of silver with production of the olive-coloured powder of oxide of silver. Chloride of silver dissolves in small quantity in concentrated hydrochloric acid, in solution of chloride of ammonium, and various metallic chlorides, and in strong nitrate of silver solution, from these it is for the most part precipitated upon dilution; it is also rather soluble in nitrate of the peroxide of mercury. Its true solvents are, however, ammonia and hyposulphite of soda, with the latter it forms chloride of sodium and a double hyposulphite of soda and silver.

Chloride of Mercury.—There are two salts of these elements. One, the subchloride or calomel, and the other the perchloride, or *corrosive sublimate*; the latter is the only salt of interest to photographers. Corrosive sublimate is not an easy salt for amateurs to make; perhaps the following is the method most likely to be useful. Grind together in a mortar 1 parts of mercury with 1 of common salt, 2 of nitre, and 4 of calcined green vitriol till the mercury has lost its fluidity, and then sublime in a glass retort. White fumes condensing to a white crust are evolved, and when these have ceased to come over and condense in the neck of the retort, they are to be scraped out and dissolved in water. The filtered solution evaporated to the crystallizing point, deposits corrosive sublimate which may be rendered quite pure by crystallization from alcohol. Thus purified it forms white tabular crystals, which when heated fuse, boil and volatilize below redness. According to Faraday corrosive sublimate evaporates even at the common temperature, but this statement is contradicted by Riegel. Its aqueous solution is acid to test paper; it has a sharp metallic taste, and is very poisonous. Exposed in solution to sunshine it is decomposed with precipitation of calomel. Several metals likewise decompose it with precipitation of either the subchloride or metallic mercury; such as arsenic, antimony, bismuth, zinc, tin, lead, iron, nickel, copper, cadmium, and silver. Corrosive sublimate dissolves in 16½ parts of water at 14° C. and in 2 or 3 parts of boiling water. It dissolves in three parts of alcohol, in 4 of ether, and abundantly in volatile oils.

Perchloride of Gold.—This important chemical may be prepared in the following way:—Pour over half a sovereign, placed in a clean glass flask, a mixture of two parts strong hydrochloric acid and one part nitric acid, and warm gently in the water bath; energetic action will at once take place, and the coin will speedily be dissolved; if the first quantity of acid which is poured over is not sufficient for this purpose more must be added. When the coin has entirely disappeared evaporate it very gently in a dish over a water bath until the solution is of a syrupy consistency; then remove and dilute considerably with water. If any white precipitate take place at this stage it will be chloride of silver and must be filtered off. Now add to the clear liquid an excess of solution of protosulphate of iron and gently heat; all the gold will be then precipitated in the form of a brown powder free from copper. This must be filtered, washed first with warm dilute hydrochloric acid, and then with distilled water. The pure gold produced in this manner must then be dissolved in nitrohydrochloric acid in the manner described above, and the solution evaporated in a water bath with excess of hydrochloric acid to a syrupy consistency, but not too far or it will be decomposed into the protochloride. It may then be dissolved in water and preserved for use. A half sovereign, containing about 56 grains of pure gold will yield about 86 grains of pure terchloride of gold, and thus if no loss has been experienced in the manipulation the strength of the solution can be readily estimated. It will be convenient to dilute it until one drachm of solution contains one grain of anhydrous terchloride of gold $Au\,Cl_3$. The solution so obtained is of a magnificent yellow colour inclining to orange; it tastes rough and bitter, but not metallic, and under the influence of light stains the skin and organic matter in general a purple red colour. Most metals, including silver and platinum, precipitate the gold from it in the metallic state; many organic compounds likewise reduce it. Oxalic acid throws down all the gold as a metallic brown powder with evolution of carbonic acid; a very dilute solution is coloured purple by transmitted light. Protosulphate of iron precipitates the metal in the form of a red brown powder which colours the liquid blue by transmitted light and brown by reflected light. This is a very delicate reaction, a solution of no more than 1 part of gold in 64,000 parts of water being capable of recognition by its means. Hyposulphite of soda added to an excess of gold solution precipitates sulphide of gold; if, however, the gold solution be added to an excess of hyposulphite of soda it dissolves with formation of a double salt.

ON PRINTING TRANSPARENCIES.

BY SAMUEL FRY.*

I now come to the gelatine method. Make a solution of

Wilson's Gelatine ...	30 grains
Water ...	10 ounces

The same arrangements of baths made here as for the albumen process, but with 3 of necessity, viz.: 1 for nitrate bath, one for distilled water, and the third containing the solution of gelatine.

Proceed exactly as previously described for the albumen, until completing the thorough washing after the distilled bath. Then immerse the plate in the solution of gelatine, and allow it to remain one minute. On removing, set up to drain corner-ways without washing off the gelatine.

When surface dry, finish up by artificial heat. The solution of gelatine of the strength above described, will almost set into a jelly when cold, and may be liquefied by slight warmth for use.

In the previous use of gelatine for dry plates for the camera, it has been recommended, I believe by Mr. Long, to add citric acid to the solution; this has, I believe, a certain effect in preserving the whites of the picture, and also has a tendency to prevent discoloration of the developing solution, but I have of late omitted its use on account of the retarding influence it exerts, thus leading to considerable loss of time.

With regard to the Oxymel preparation, I use that as before described, of the strength of 1 dram to 4 ounces of distilled water, and applied in the same manner as the gelatine. The same bath of gelatine and oxymel may be used for about three dozen plates.

Our plates are now ready for exposing, and to effect this properly, a small printing frame the exact size of the plates should be employed, though not indispensable.

In larger frames the negative or prepared plate may be scratched from slipping about on the smooth surface of the glass. The front glass of the frame should be very carefully wiped and dusted out, and the surface inside and out polished, as smears are often represented on the surface of the pictures, when printed, through their being imperfectly cleaned. In a yellow light place the negative inside the frame, picture side uppermost, lay the prepared plate on it very gently, and endeavour at once to put it in its exact position, and not allow it to slide about on the surface.

Over the prepared plate put a padding of felt, and then fasten the lid firmly down. This done, carry the frame and expose it to a north light: for a weak negative, 5 seconds is ample; one trial will generally suffice to indicate what the true exposure should be.

To develope, remove the plate very carefully from the frame, and immerse it in a bath of distilled water. For the oxymel process it suffices to merely wet the surface of the plate; but the albumen plates should soak for two minutes, and the gelatine for five: the developers I use are,

For albumen and gelatine:—

Pyro ...	1 grain
Citric acid ...	½ grain
Water ...	1 ounce

For oxymel plates:—

Pyro ...	½ grain
Citric acid ...	½ grain
Water ...	1 ounce

also make for use during development a 20-grain solution of nitrate of silver, and use it for no other purpose. We must bear in mind that the plate having been deprived of all but an homœopathic trace of its free nitrate, more must be added, and acting with the developer before any image can be produced.

To develope, take 2 drams of the solution, and 6 drops of silver, pour it quickly over every part of the already wetted surface of the plate, and move it well from one side to another. The oxymel plates begin to develope the instant the solution is on, and are rarely more than a minute before complete.

There are few of the difficulties of negative development about the process we are now performing. The eye can observe each accumulation of density, and can apprehend the exact moment when the application of water should arrest it. Though the albumen and gelatine plates occupy rather more time in development than the oxymel, I do not look upon it as any drawback to their usefulness. On the contrary, ample time is allowed to judge when sufficient density is acquired.

Those pictures should be essentially transparencies, even

* Continued from p. 218.

the deepest shades should be semi-transparent, and the whites clear and unclouded.

The effects of under and over-exposure are more easily observable than in a negative, the former giving a black-and-white patchy image, and the latter a hazy, cloudy affair, very dim and indistinct, coming up far too quickly under the developer, whilst the under-exposed plate, for a long time, shows no result whatever; and, after giving more trouble and using more developer than half-a-dozen good plates, is useless. The tendency is to over-expose, and, for that reason, I am partial to exposing the plates in an ordinary room, at about a yard inside a shady window, where a definite exposure of, say 30″, is required. Where the time is here once nicely hit upon, a considerable number of pictures may be obtained in a short time.

I have sometimes found, in winter time, the citric acid in the developer had a powerful retarding action, and have then substituted acetic acid, but not frequently. I invariably use cyanide of potassium for fixing, but recommend a weak solution, such as will require two minutes to dissolve the iodide.

When thoroughly washed, set up to dry, preparatory to the next operation, which is that of scraping away the film at each end and round the sides of the plate.

This operation gives a very pleasing finish to the pictures after mounting, and is in every way to be preferred to the plan adopted by some of putting a black paper mount between the transparency and ground-glass. In order to be able to rule lines mathematically straight down the ends and sides of the transparency, it is indispensable to fix the plate firmly with the film uppermost. This is best done by fastening wire pins into a board of eight inches square, in such a manner that they may project above the board one-eighth of an inch, and allow a stereoscopic plate to be dropped between them. The ruler I recommend is a straight piece of boxwood, nine inches long and two inches wide, having at each end a slip of wood one-eighth thick and one inch square glued on. This ruler may be moved over the stereo. plate without touching the film.

With this ruler, and a very fine bradawl, or any pointed tool, draw lines along the film three-eighths of an inch from each other, and three-sixteenths from each side, along the entire length. With a knife, or pair of scissors, carefully scrape off all the film outside these lines.

Some pictures require a line ruled down the centre, but this is not invariably the case. Be very careful to remove, with a soft broad camel-hair brush, any particles of dust; then pour over the picture a thin, transparent varnish, of such as used for collodion positives—it cannot be too thin, or too free from specks. It should always be filtered after use, as the smallest hair, or piece of floating matter from the atmosphere, is detected on these pictures.

And now with regard to the mounting and finishing our picture. Two methods are available. The first is to simply bind a fine greyed glass over the picture, the rough side next the film. This beautiful plan is so well known, that it would be waste of words to describe its appearance; but the second means is intended for those who are in places where these finely-ground glasses cannot be obtained, and consists in adding to any good crystal varnish about sixty grains per oz. of white wax. When this mixture is poured into a cold, thin stereoscopic glass, it quickly sets, and forms as good a medium as can be desired to show up the transparency. It is placed waxed side inwards, and bound round with a thin ribbon of dark-coloured paper. The appearance, I believe I may say, is quite equal to the ground-glass, and much less expensive.

The utmost care is necessary to pour the wax varnish on the surface very smoothly, as any waves are very distinct in the stereoscope.

The ribbons of paper to bind the pictures together should be three-eighths of an inch wide, and of a length to go quite round the picture at one operation.

The best material for sticking them on, I find, is glue, as it sets firmly at once, and is air-tight to a greater extent than paste, or most cements. I have given every branch in tolerably full detail, because I well know the difficulties that beset beginners, and, in conclusion, cannot too strongly recommend the readers of the News to try one or all of these very simple processes, which produce exquisite pictures, and are most simple of practice.

Proceedings of Societies.

The London Photographic Society.

The usual monthly meeting was held on Tuesday evening, the 7th instant, at King's College; Mr. Henry White in the chair.

Captain Willoughby Osborne, H. Hailstone, Esq., and Col. Maitland were elected members of the society.

The Secretary read a letter from Mr. Lazarus, Secretary of the Bengal Photographic Society, remitting the sum of one hundred pounds collected in India in aid of the Archer Fund.

Mr. Thomas then read a paper entitled, "How to prevent Stains and Streaks in the Negative." Passing over a variety of easily traceable causes of stains, &c., such as damp or dirty clothes for polishing the glasses, he expressed his conviction that the most prevalent cause was too much light in the dark room. Photographers were, he observed, in the habit of working at the present day with their dark rooms admitting as much yellow light as they did several years ago, forgetful of the increased sensitiveness in which improved preparations communicated to their excited plates. Streaks in the direction of the dip were, he said, caused by the plate being lifted out of the bath, and exposed to the excess of yellow light, whilst the bath solution was standing on the plate in greasy lines, and the action of light on the plate in that condition produced these lines. Nine-tenths of the failures which occurred he attributed to this cause. He then detailed some experiments, and produced the negatives which, he conceived, illustrated his position. He concluded by stating his conviction, that a proper over-hauling of the dark room, in order to take every precaution against the presence of actinic light, would prove an effectual remedy for the majority of troubles arising from this cause. No kind of yellow or orange glass, he believed, was sufficient alone to prevent actinic action.

Mr. Bedford, in reply to an appeal from the Chairman for his opinion said, that he worked with so much light in his dark room, and yet got satisfactory results, that he felt unwilling to make any remark on the subject. He certainly could not entirely go with Mr. Thomas in regarding this as such a fertile source of failure. It was undoubtedly essential to take every precaution to avoid the presence of diffused white light; but he thought a sufficient amount of yellow light was desirable. Had Mr. Thomas ever developed a plate without any further exposure than that to which it was submitted in the dark room to see if it produced streaks? He remembered that some of the most brilliant negatives he ever produced were taken at Marlborough House, on plates 8 by 5, and he there only used two thicknesses of yellow calico over the window. He there had sufficient yellow light to read the smallest print in any part of the room, and yet the negatives did not fog, streak, or stain. When he had been troubled with those streaks, he had tried darkening the room with additional yellow calico; but, although it made the room very inconvenient to work in, it did not remove the streaks. He did not think Mr. Thomas had indicated the true cause.

Mr. Vernon Heath asked what aspect the window had at Marlborough House to which Mr. Bedford had referred.

Mr. Bedford: Nearly south.

Mr. Heath thought it was due to Mr. Thomas to mention his experience during the last few weeks. He had been much troubled, whilst working in his glasshouse in London, with stains, and Mr. Thomas had pointed out the cause as being too much light in the dark room, although it was lighted with ordinary care. He had altered it according to Mr. Thomas's suggestion. The streaks at once disappeared, and he obtained brilliant negatives, with printing qualities to which others he had obtained in the room bore no comparison. The streaks ran from the top to the bottom of the plate, and he found they could be produced at will by the action of light.

Mr. T. R. Williams, in answer to the chairman, remarked, that whilst streaks might undoubtedly be caused in that way, he did not think it was the common or ordinary cause.

Mr. Malone said he remembered that Mr. Crookes, in fitting up his dark room, placed a sheet of yellow glass in the shutter, put an excited plate opposite to it in full sunshine, and then developed it. By this means he at once was enabled to detect the slightest photogenic action. When the dark room at the London Institution was being fitted, Mr. Bedford, he remembered, had suggested the use of yellow calico as well as yellow glass in a case where the glazier had not put in the deep tint of yellow which had been selected. It was important to conduct operations in a systematic manner in testing for the presence of actinic light, as it was quite possible to have the room so dark as to be impossible to work in it, and yet not be entirely free from the presence of actinic light. It was well known that a dirty plate would sometimes cause reduction without the action of light, and it was quite reasonable to suppose that the slightest dirtiness of the plate, not sufficient to cause reduction and stains in itself, might, by the presence of a very small amount of diffused actinic light, be assisted to set up an action, and thus cause stains. The mode in which the streaks referred to were caused by the action of diffused light, was, he presumed, due to the greasy lines present when the film was first lifted out of the bath, refracting the light, and thus producing increased action just in those parts,

Mr. Sebastian Davis thought that the action of light was by no means always the cause of these streaks. He had recently been preparing some dry plates, and for economy of time had two baths in use. One of these gave streaks, whilst the other did not; the former being a very old bath having excess of ether. He used orange glass and a covering of yellow paper. He thought it important to have a means of regulating the amount of light for bright and dull days.

Mr. Malone remarked that the yellow flashing did not always perfectly cover the glass, and it might be desirable then to use two thicknesses, or calico as well. It was possible that the streaks occurred from light only, when the plate was in the highest possible state of sensitiveness.

Mr. F. G. Eliot said the lines occurred sometimes when there were no fogging tendencies. If the plate were lifted out of the bath at an early stage, and kept out long, streaks would occur, which would be prevented if it were moved up and down quickly, notwithstanding that the aggregate amount of time which the plate would be out of the bath was equal to that which would have produced stains if kept out at one time. This appeared to contradict the idea that it was caused by light. There was always less danger of the streaks with a collodion containing a full proportion of alcohol.

Mr. Thomas, referring to Mr. Bedford's statement regarding his operating at Marlborough House, remarked that he believed that this was some six or seven years ago, and that the nitrate of silver then used contained much nitric acid; the collodion was chiefly iodized with potassium; and the pyroxline then used was of that quality which soon decomposed, so that everything at that time was in a less sensitive condition than at the present time, and that now, therefore, additional precautions were necessary. In reference to the use of orange, or yellow glass, he could not allow that it was ever sufficient to protect sensitive wet plates from the action of light. He had not had much experience in dry collodion, and for his own part he wished all dry collodion processes were at the bottom of the sea, because they had superseded the most beautiful dry process in his opinion, the calotype paper process, the results of which were superior to anything produced by dry collodion plates that he had ever seen.

Mr. Malone protested against the assumption that orange glass might not be procured, which would entirely intercept actinic light, if not always in one thickness, at least in two. Mr. Crookes' experiment was conclusive on that subject, and he was too good a chemist to use a nitrate bath containing nitric acid in such an experiment; if that were the assumption which was to meet Mr. Bedford's experience. Mr. Thomas of course could speak definitely in that case, as he had sold Mr. Bedford the nitrate of silver containing this free acid.

Mr. Thomas would be very glad to meet with the yellow glass which would thus stop out actinic light, as he had been unable to procure any.

Dr. Diamond said that yellow glass might be used for such a purpose, there could be no doubt, as it was in Archer's camera, without any fogging whatever. As for the streaks referred to, he had never met with them in his own practice.

Mr. Sutton remarked that he had used a vignetting plate of red glass in printing transparencies, and no action of light was observed under the red glass.

Mr. Harvey then read a paper on ancient and modern methods of preserving works of art, of which an abstract will appear in our next. The paper was illustrated by several handsome portfolios made on Mr. Harvey's patent.

Mr. Vernon Heath gave notice that at the next meeting he would bring under the notice of the society the anomalous position in which photography was proposed to be placed in the Exhibition of 1862.

Dr. Diamond stated that the Chief Baron had received a communication from the Commissioners requesting the Photographic Society to appoint six or eight persons to advise with them regarding arrangements for the representation of photography. A meeting of the Council was at once called, and it was resolved that photography ought to be placed in its right position before photographers could take any part in the matter. The Chief Baron had, therefore, written a remonstrance to the Commissioners, which he hoped would have the effect of bringing about the desired result.

Mr. Heath thought that this was highly satisfactory. When he first saw the announcement of the classification he thought it must have been a mistake, as photography could never be intended to rank as a simple mechanical operation. How was it there was such a striking individuality in the productions of different photographers? The distinctive styles of men like Bedford, and Fenton, and Lyte, were just as distinctly marked as those of the masters in painting. This distinctiveness, as artistic excellence, was alone surely enough to prove the right of photography to a place amongst the skilled arts, and rescue it from being regarded as purely mechanical.

Mr. Shadbolt suggested that if photography were not properly placed in the Exhibition of 1862, photographers should not exhibit there, but that a contemporaneous Photographic Exhibition should be got up, disassociated from that undertaking. He might mention that a correspondent of the British Journal had suggested that it would be well if the space could be so arranged as to allow of the works of different societies being kept together, so as to secure the emulation of societies as well as of individuals.

Mr. Malone stated some of his personal experiences in connection with the Exhibition of 1851, having been appointed at the last moment on a sub-committee to attend to the matter; and he well remembered the hostility of feeling then manifested to any consideration of photographs as works of art. Some specimens arrived late which were coloured, and the photographer who had sent them contrived to get them into the fine art department. He (Mr. Malone) pointed out the anomaly, and simply received for answer that the photographer who had sent them was a noisy troublesome fellow, and they had better remain where they were. He feared a similar spirit was likely to prevail in regard to the Exhibition of 1862.

Mr. Durham said, that the suggestion of the council was that photography be removed from the class devoted to the mechanical arts to that devoted to fine arts.

Mr. S. Davis thought that touched photographs ought not to be admitted, as the very fact of touching gave countenance to the idea that photographs were not sufficiently perfect as works of art without the aid of the pencil.

Mr. V. Heath said, that he hoped to be able to exhibit Professor Way's Electric Lamp at the next meeting.

The proceedings then terminated.

Newcastle Photographic Society.

The monthly meeting of this Society, held on Friday evening the 4th inst., in the Carpenters' Tower, was a highly interesting one, and was crowded to excess. Mr. J. C. Warren, one of the vice-presidents, presided.

The Chairman read a circular he had received from the hon. secretary of the Birmingham Photographic Society, notifying that they intended holding an exhibition of photographic pictures, and offer silver and bronze medals for the best specimens in the various departments of the art, towards the end of the present month.

The meeting then proceeded to the trial of a number of experiments with the Photogen, the invention of Mr. Moule, by the aid of which several portraits were taken in the room—Messrs. Laws and Warren, of Newcastle, and Mr. Hill, of North Shields, assisted by Mr. North and Mr. Porteus, operated.

In a letter which accompanied the apparatus, Mr. Moule informed the secretary that he had sent out to Bengal, by order of the Government, two of these lights and apparatus complete, to be used for the purpose of taking the interiors of caverns in India, which can only be done by means of artificial light. He also stated, that during the last season no less than 300,000 portraits had been taken by artifical light, and that portraits by the photogen were becoming general in London.

The Chairman also exhibited, explained, and manipulated with the pistolgraph—an ingenious little instrument for taking portraits—so small, indeed, that a box 3 inches by 2½ inches would contain it. The experiments were entirely successful.

The utmost satisfaction was expressed with the portraits and transparencies exhibited, the result of the experiments by the council, a conviction being expressed by many that portraits taken by the aid of the photogen were equal to any taken by daylight.

A resolution was passed expressive of the high opinion entertained of the photogen by the society, and intimating their conviction that the testimonials, &c., given to Mr. Moule were well deserved. Also, that portraits taken by the aid of the photogen were equal in tone, strength, and delicate shade to those by sunlight. A vote of thanks was also given to Mr. Moule for the readiness with which he forwarded the photogen for exhibition to the society on learning the council's wish.

Mr. Law's paper on transparencies was postponed by desire of the council, in consequence of the receipt of the photogen.

Votes of thanks to the Chairman for presiding at the meeting, and to the operators for their interesting experiments, concluded the proceedings.

The exhibition of the photogen produced considerable excitement, outside as well as inside the meeting, many hundreds of persons being attracted by the light.

[Mr. McKie, the honorary secretary, has forwarded us a print of one of the half-plate negatives taken in the meeting by means of the photogen; a portrait of one of the reporters on the *Newcastle Daily Express*. It is in no respect inferior to many photographs taken by the solar light with all "appliances and means to boot."—Ed.]

Critical Notices.

THE PRINCIPLES AND PRACTICE OF PHOTOGRAPHY FAMILIARY EXPLAINED; Embracing the Collodion Process; Printing on Plain and Albumenized Paper; How to produce Life-size Portraits; Dry Plate Photography; Colouring and Mounting Photographs; Defects, Failures, and Remedies, &c., &c. By C. Jabez Hughes: London, 379, Oxford Street.

There are few things so difficult to accomplish as to write a good elementary book, which shall not be *only* an elementary book; to give the most simple instructions in the most familiar and popular manner, and yet convey information for constant reference, of abiding value to the expert, as well as to the enquirer on the threshold of science. It is not only necessary that the author shall understand his subject intimately, having pursued it through every phase of circumstance, but that he shall also have the gift of teaching; that he shall have the happy art of investing the recondite and abstruse parts of his subject with the familiar aspect which makes them seem easy; and so deal with those things, which, from their apparent simplicity and common-place character, are apt to be overlooked, that they assume an uncommon face, and so gain the attention which their real importance demands. Amongst the multitude of manuals of photography which the actual demand, the *cacœthes scribendi*, and trade exigencies have brought into existence, and amongst which there are already good, bad, and indifferent guides, we know of none superior to the little work before us. Possessing all the qualities of most other first books, it also has some distinctive features peculiarly its own. The style in which it is written is pre-eminently a happy one. The instructions are addressed to a pupil supposed to be present, and the easy, familiar, and colloquial style of addressing a definite personality is adopted. This is, however, never allowed to run into digression or discursiveness. The air of a thorough master, too much in love with his art to run away from it, is manifested throughout.

A chapter on the use of diaphragms or stops is the most complete on this important subject we have seen published; in too many works the subject is passed over with merely a passing allusion. The chapter devoted to copying and enlarging is also very complete, and will prove a valuable guide to others besides the mere beginner. "How to arrange the lenses in a portrait combination" is the heading of a chapter which will place the photographer in possession of information at once which will prevent him troubling the optician or dealer, by complaints of a bad lens, simply because he has unconsciously contrived to misplace some lens in the combination. The student of dry photography will find very complete epitomes of the collodio-albumen, the Fothergill, and the tannin processes.

The chapter on "Defects, Failures, and Remedies" will be of interest and value to every reader and will be one of the first referred to by all who have had any experience. It is one of the most complete and comprehensive chapters ever published on the subject, not less than twelve pages being devoted to the extrication from this inevitable photographic "hill difficulty." The opening paragraphs in this chapter are so much to the purpose, and are so characteristic of the excellent style in which the book is written, that we will quote them here:—

"However it may be in other mortals, for a certainty, 'tis not in photographers to command success; and although I have given you clear and simple directions, which I have no doubt you will carefully follow, yet, My Worthy Pupil, I fear that you will not be exempt from many of those troubles which most of us have encountered.

"It may be a melancholy satisfaction to know that the cleverest practitioners are subject to them in common with the less skilful; the difference, however, being, that the former by perseverance overcome them, while the latter give up the contest and are beaten.

"As you have, no doubt, determined to belong to the first class, and with a view to aid you, I enumerate the most probable causes of failure.

"Generally speaking, to point out the origin of a defect is also to suggest a remedy; when, however, this is not evident it will be stated. It is impossible to anticipate where your difficulties will be, for the experience of no two exactly agrees, but you must endeavour to *understand* the process, and to grasp the *spirit* of the directions. Above all things resolve to be neat and clean in your manipulations, cool in your manner, and exercise an observing eye, and you will certainly escape from nine out of ten of the beginner's troubles.

"Whether a person shall succeed or fail in photography depends very much on the spirit with which he commences. If he thinks the whole process a *mechanical* one, mainly a question of apparatus, baths, and developers, he has no pleasant future. When he gets into difficulty—and he soon does—he declares his chemicals are wrong, his bath is out of order, is camera is bewitched, and rushes from shop to shop to buy the last 'patent never-fail collodion,' or the marvellous greek-named lens that takes pictures in a few seconds less than no time, or some other be-puffed and be-advertised nostrum, instead of stopping at home and quietly finding out in what his trouble consisted. Possibly he has mixed his plain collodion and iodizing solution in reversed proportions, or strengthened his nitrate bath out of the unlabelled hypo bottle, or been trying to develope with his cyanide. Such a man soon wears himself out, declares, 'it's no use trying, it's all chance,' and attributes the success of skilful men to the use of 'secret dodges.'

"As a contrast, observe another man, who begins quietly and steadily, and, getting into trouble, thinks it very probable that it is *he*, not the chemicals, that is wrong; and instead of throwing them down the sink, perseveringly proceeds, finally discovering that the same chemicals that gave him bad pictures now furnish good ones, the difference being only *in the mode of using them*. A man of this stamp, taking pride in his new acquisition, and not blind to his own deficiencies, reads the Journals, joins a Photographic Society, compares notes with his confreres, keenly enjoys a visit to a Photographic Exhibition, and speedily becomes an intelligent and clever manipulator."

Mr. Hughes has a high appreciation of the value to the progress of the art of photographic journalism, in which opinion we, of course, cordially agree with him. In his preface he remarks that "to the Journals is mainly due the vast diffusion of Photographic knowledge and wide-spread practice of the Art. They are so varied in their contents, the most elementary to the profoundest subjects being freely discussed, that the pupil can scarcely peruse a single number without obtaining valuable information; and no better advice can be given to the student who would perfect himself in the Art than to read them carefully."

Both to the beginner or the advanced student we can cordially recommend Mr. Hughes's book. His long practice, well-known skill, and intelligent appreciation of the science and art in all its bearings, enable him to speak with authority, and he possesses the happy art of speaking so as to be thoroughly understood. The book is crammed full of information, and will, we doubt not, soon be in the hands of all interested in photography.

CARTE DE VISITE PORTRAITS.

We have received from Messrs. Squire and Co. some samples of an elegant application of mica to the protection of visiting card portraits, which they issue under the title of "silicious laminæ." It is, of course, as transparent as glass, but as thin and pliable as paper. Placed over the portraits in the small cases prepared for their reception, they at once improve the appearance and afford complete protection from abrasion or soiling of the surface. Messrs. Squire and Co. possess unusual facilities for supplying the sheets of mica for this purpose, and also for photographic purposes generally, entirely free from imperfections. Being the patentees and manufacturers of the mica illuminated letters for attaching to shop windows, &c., very large quantities of this material pass through their hands, and they are thus enabled to assort the different qualities, and apportion each to its proper use. The finest specimens only are suitable for photographic purposes, whether as a support for the collodion film, or as a protection to the card portrait.

Whilst referring to the subject of visiting cards we may remark that we have received from Mr. St. George some very fine specimens, consisting of portraits of public characters which have been forwarded as samples of the work done at his printing establishment. The negatives are we believe also his production in his capacity of operator at Mr. Clarkington's establishment. The printing is very fine indeed; clean and vigorous, and remarkably rich in tone. They are highly satisfactory both as photographs and portraits. We may here take the opportunity of remarking in reference to the price for printing visiting cards, regarding which we had some correspondence a few weeks ago, that Mr. St. George informs us his price for this work is two shillings a dozen.

NEWMAN'S ILLUMINATING COLOURS.

We have received from Messrs. Newman, of Soho Square, some samples of their new colours, prepared especially for the recently revived beautiful art of illuminating. Incidentally, however, they possess another valuable feature, interesting to the photographer; they are essentially well suited for colouring backgrounds, in either paper prints or glass positives. They are easily applied, possess much vigour and depth; and dry perfectly "flat" or dead, without giving the flat, inartistic effect usually produced by the dead back grounds in which body colour is used. We shall make some further experiments, and report as to details of manipulation.

Photographic Notes and Queries.

THE TANNIN PROCESS.

SIR,—The suggestion made by you to take a hair pencil and dip it in a solution of albumen (3 water and one egg) and to pass a thin film of it (which on drying becomes almost invisible) of the breadth of one-eighth of an inch round the edge of the plate in order to attach the collodion for the tannin process, is complete in its success. It does not interfere with the definition of the picture to the edge, and I have washed plates 8×10 with a strong flow of water, and the collodion adhered well: but to check the possibility of cracking, I began the development by adding at least three ounces more of water to the albumen, and pouring it over the plate. The plate was collodionized one day, exposed the next, and developed in the evening. Nothing went wrong, and the film was flat and adherent. Five grains of tannin to an ounce of water alo quite enough. F. F.

THE COLLODIO-ALUMEN PROCESS.

SIR,—I shall feel obliged if you or any of your correspondents practising the collodio-albumen, would describe the best plan to wash the stereo plate *after the last sensitizing*. I have read attentively every article in the NEWS from the commencement, and have practised the above with pretty good success, but still think further information required. I can well understand that you are not likely to over-wash the plate after the first bath, but it appears to me from my experience that some limit or system is necessary to obtain *uniform* results, in the last washing, to do just sufficiently, and no more, for the plates to keep, say about two weeks in summer? Mention has been made once or twice in the NEWS respecting a final wash in a weak solution of salt and water, but not sufficiently explicit.

2nd. In working with wet collodion which developer will bring out the picture with the *least* exposure, *iron* or *gallic* acid?

3rd. In your opinion, which is the best way "following the method recently described in the NEWS, pouring a small quantity of water over the exposed plate before development" to add the acetic acid to the water, or to keep to the usual formula, mixing the acid to the iron solution.

4th. Which is really the best way to intensify after developing with iron, to flood the plate with a weak solution of silver and acid, and continue the iron development, or intensify with pyrogallic as of old?

5th. I have just now been trying two plates from the formula mentioned in last Friday's NEWS, page 207, Hannaford's method. I have seen nothing to excel them as negatives, they develop clearly and free from stains, markings or blisters, the exposure shorter by a minute than collodio-albumen; but as I only prepared the plates on Saturday, exposed them in a day or two, and developed them at once, I cannot have any idea how long they will keep, so that my fifth question resolves itself into this: Can you suggest a way that plates prepared by the Michael Hannaford method will keep about 8 or 10 days in summer.

With my best thanks for former answers, I am, yours sincerely, W. S.

[A thorough final wash of the excited collodio-albumen plate is necessary in order to ensure good keeping qualities, and clean even development. We believe this is the practice of of Mr. Mudd, the best collodio-albumen operator we know. Where a final wash in salt and water is adopted there is sometimes a tendency to want of vigour, but a wash of gallic acid after the salt and water, has been found to remedy that. 2. Wherever iron can be used as a developer, it is undoubtedly more energetic than gallic or pyrogallic acid, and brings out a latent picture with less exposure. 3. Pour a little water without acid over the plate, and have the acid mixed with the developer. In some cases it is thought that the application of acetic acid to a latent image would destroy some of its most delicate tones. If the light have any tendency to oxidize the parts of the silvered film on which it acts, the addition of free acetic acid might cause the formation of acetate of silver. 4. The simplest method of intensifying is simply to wash the plate, after bringing out the details with iron, and apply a pyro developer and a little silver until the right density is obtained. 5. Mr. Hannaford believes that plates prepared on the plan he has suggested will keep as long as Fothergill plates. Experiment must decide the question.—ED.]

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 8th May, 1861.

M. Poitevin has communicated an interesting paper on certain photographic processes upon which he has experimented. It has been observed long ago that the salts of the sesquioxide of iron are brought to the state of salts of protoxide, by the action of light in presence of certain organic compounds, such as alcohol, ether, &c. Desiring to apply this property to photographic printing, M. Poitevin sought for non-volatile reducing agents. The salts of the sesquioxide of uranium reduce themselves by the action of light in presence of organic bodies, as paper, for example, react upon the salts of iron, by the salt of protoxide of uranium, which is first formed: acetate of ammonia, alloxanthine, glycerine, and especially tartaric acid, also give very definite and useful reactions in photography. Although this reduction is common to all the salts of iron, and even to the protoxide of iron, which M. Poitevin also experimented upon, he stopped with the employment of a mixture of perchloride of iron and tartaric acid. These observations will be confined to these two substances.

The partial formation of gallate of sesquioxide of iron on paper and on other substances to produce photographic images, is based upon the reduction of the perchloride of iron into the protochloride, which is formed only in those places which are submitted to the action of light.

The application of powdered carbon and coloured pigments or vitrifiable bodies rests upon another property, which M. Poitevin thinks he was the first to take notice of: this is, that perchloride of iron and tartaric acid, dissolved in certain proportions, and applied upon any given surface, then dried, either artificially or spontaneously, in the dark, give a uniform coating of a non-crystallizable and non-hygrometric compound, and which remains in that condition so long as it is not exposed to the action of light, but which becomes deliquescent in the sun or in diffused light. In the parts influenced by light, M. Poitevin ascertained the presence of protochloride of iron, which is very deliquescent, and of a body possessing an acid reaction, and very attractive of water, which is formed by the reaction of chlorine upon tartaric acid: it is this last product especially that plays the most important part in the application of the dry powders upon the photogenic surfaces employed, for there is not sufficient formed to make the colours adhere when the proportion of tartaric acid is diminished.

The following is the modus operandi:—

1st. To print with *gallate of iron* (ordinary writing ink) make a solution consisting of 10 drachms of perchloride of iron in 100 drachms of water; then add 3 drachms of tartaric acid, filter the solution, and preserve it out of the action of light. To prepare the paper, pour this mixture into a dish, and float the paper on its surface, carefully avoiding bubbles; it is lifted out immediately, drained, and hung to dry in a dark place, or it may be dried at a gentle fire. The paper prepared in this manner may be preserved in a state fit for use a long time. Its colour is deep yellow. When to be printed on it is put into the pressure frame, under a negative or other design to be reproduced, and exposed to the light until the yellow colour of the paper as seen through the negative has disappeared, and an image of a deep yellow colour appears on the white ground of the paper. To convert this image into a picture in black ink, the impressed paper is plunged into distilled water quickly, and afterwards into a saturated solution of gallic acid, or into an infusion of nut-galls, or preferably into a mixture of gallic and pyrogallic acids, according to the blackness of the tone it is desired to obtain. In either case the organic acid forms ink only on the parts where the perchloride of iron has not been decomposed, and is without action on the protochloride which covers the other parts of the proof which have received the action of light. In this manner a direct impression is received. To fix the image it is only necessary to wash the proof in distilled or rain water.

2nd. Carbon printing, and printing in powdered colours, painting upon porcelain, enamel, &c.

In practising the preceding mode of photographic printing, it has been remarked that the paper became very permeable to water in those parts which received the action of light. This property, M. Poitevin turned to account to form images with various coloured powders; to this end it is sufficient to moisten the back of the paper with gum-water, which passes through the paper and retains the powder-colours applied with a brush. Subsequently, upon substituting a ground-glass surface for the paper, and covering it with the mixture and drying it, it was remarked that after exposure to the light passing through a negative, the parts influenced became humid spontaneously, and that the preparation, from being dry, had become deliquescent in those parts only; this fact suggested a new mode of printing, which may be described as follows:—

Make two solutions, one containing 10 parts of perchloride of iron to 100 parts of water, the other of 8 parts of tartaric acid in 100 parts of water; equal volumes of these two solutions are mixed together in such quantity as may be required. Upon the surface of a finely ground-glass plate well cleaned, or even upon a plate of polished glass, previously covered with collodion or other medium; the above-named mixture is evenly poured, allowing the excess to drain off. The plate is left to dry spontaneously in the dark, placed in a horizontal position, or dried at the fire, according to the thickness of the coating of the preparation it is desired to obtain. The plate, when dried may be kept, in the dark, a long time fit for use. The impression is made through a negative; the time of exposure will be about five to ten minutes in the sun; the time varies according to the season and the intensity of the negative. On removal from the pressure-frame the design is scarcely visible on the plate; but it soon becomes so in the humid portions which have been acted upon by the light. This humid portion admits of the coloured powders adhering to the plate, wherever it exists, and the design gradually appears under a brush charged with dry colour. The picture may be preserved in this state; it is permanent, but it is better to remove with acidulated alcohol and then with water, those portions of the mixture which have experienced no modification by the action of light, they are insoluble in pure water; the plate is then dried and varnished. By this process a transparency is obtained. If a painting on glass is desired, mineral oxides or enamels are employed as coloured pigments, and the glass plates placed in muffle furnace at a temperature sufficient to fuse the flux or enamel; porcelain or enamelled surfaces are treated in the same manner.

When only a proof on paper is desired, powdered carbon or other pigments, insoluble in water, are employed, and the paper on which the design is impressed is covered with a layer of simple collodion, then wash the paper with acidulated water to remove the excess of the preparation, and destroy the adherence of the collodion to the plate, and the coating is removed by means of gelatined paper. No trace of the design remains on the surface of the glass. The image may be gummed or varnished to solidify it, and the proof glued on cardboard.

It was also remarked that this preparation of perchloride of iron and tartaric acid possesses the property of retaining fatty bodies only those parts which have not received the action of light, and affords a means of photographic impression in fatty ink, and of chemical engraving.

It is often desirable to repair the damaged silvering of looking-glasses, but the operation is very difficult. The following process is the result of several experiments, which assure success if proper skill be exercised. The spot denuded of silver is carefully cleaned from dust and grease with a tuft of cotton, so that no stain remains around the margin.

Then with the point of a knife cut out a piece of the silvering from another piece of looking-glass, a little larger than the place to be prepared. Upon this a globule of mercury, say as large as a pin's head, for a piece of tin the size of the thumb-nail. The mercury spreads immediately, and penetrates the tin as far as the margin marked with the knife's point, and permits the tin being removed to the place to be repaired. This part of the operation is the most difficult, when successful, the spot is gently pressed with a piece of cotton, it unites with the other portion of the silvering, soon becomes hard, and the new piece cannot be distinguished from the old.

THE STEREOTROPE.

Sir,—Will you allow me to offer a few explanatory remarks in reference to Mr. Clarke's criticism of the stereotrope, which appeared in your impression of the 26th ult.

First of all, as to only half the picture being visible. This was purely an accident, and was occasioned by some person having unwittingly pushed forward the mirror, so that it intercepted the view to the extent of very nearly one-half, as stated by Mr. Clarke. Upon discovering this mishap, I instantly rectified it, and, by inserting a small paper wedge, prevented its recurrence during the remainder of the evening. I need hardly say that the conical apertures are made to subtend exactly, the pencil of rays coming from the picture, and that to enlarge them would consequently serve no purpose.

I am not, however, surprised that Mr. Shadbolt, under the circumstances, should have suggested that alteration, and can only regret that he, together with Mr. Clarke and other gentlemen, should have examined the instrument at such an unfortunate moment.

Then as to the jerking appearance of the steam-engine, I am bound to admit that certain of its parts, viz. the fly-wheel and the governor, moved in a spasmodic and irregular way, not, however, for the reason assigned by Mr. Clarke. I have only a single remark to make about the governor: the pictures, in consequence of my overlooking the fact that its speed was relatively greater than that of the engine itself, did not fulfil the conditions of a perfect revolution. It should, while being photographed, have been thrown out of connection and moved-on an eighth between the several pictures of the series. The cause of the to-and-fro movements of the wheel will be readily understood from the following considerations. If I photograph a wheel which has *eight* spokes at *eight* equal intervals in a single revolution, the pictures will be exactly alike, because the spokes are all identical as to size and shape; and such a set of pictures in the stereotrope would exhibit the wheel as absolutely stationary. If, however, as in the case of the eight pictures in question, there be *six* spokes in the wheel, the effect becomes more complex, some pictures of the series being alike, and others different; whereas they should all differ in a certain definite degree. This difficulty in representing wheels in movement may be overcome in the following way. Supposing that you are about to take *eight* consecutive pictures, move the wheel on between each, *not* one-eighth of its entire circumference, but *one-eighth* of the distance between any two of its spokes. This expedient, which I have tested experimentally, results in a beautiful steady equable movement of the wheel. In regard to the wide issue, raised by Mr. Clarke, that it is impossible to exhibit continuous movement by means of pictures which represent merely certain stages of those movements, I have simply to appeal to the facts. However improbable it might, *a priori*, seem, it is nevertheless true, that the imagination supplies perfectly all that is wanting to a perfect delineation of the movements, in the pictures themselves, provided always that the difference between any two proximate pictures be not too great.

This very curious and interesting fact forms an essential feature of Professor Plateau's beautiful invention, the Thaumatrope, to which I have merely applied the stereoscopic principle, together with certain modifications, which give a clearness and minuteness of definition, which were not attainable in the simpler form of the instrument. In the hope that these observations may not be altogether destitute of interest to the general body of your readers, and that they may be held to meet adequately the objections of Mr. Clarke, the spirit of whose remarks I most heartily appreciate, I am, sir, yours respectfully, Wm. Thos. Shaw.

10, *Clarendon Villas, Mildmay Park, N., May 6th*, 1861.

NEGATIVES WITHOUT A SILVER BATH.

Dear Sir,—With some degree of pleasure I send you my method of taking positives or negatives without a nitrate of silver bath. Although I have been busily engaged in bringing it to a somewhat manageable process, it is not so perfect as I could wish; but still I think it very satisfactory for what it is, and promises to become of some practical value. After giving up several methods by which I obtained faint impressions, I found the following the most satisfactory. I first coat a glass plate with plain collodion, containing no iodide or bromide; when dry, or nearly so, I coat over again with an alcoholic solution of iodine, about the colour of port wine. This as it is, of course, is not sensitive to light, but becomes so upon the application of a weak alcoholic solution of nitrate of silver, poured on the same as collodion, it is made as follows:—

Alcohol	1 ounce
Aqua dis.	1 ounce
Nitrate of silver	10 grains

This must be kept moving over *the plate* until the yellow iodide of silver is formed; when this is complete, drain off and expose, return without loss of time to develop; to accomplish this, I first wash until greasiness disappears, then develop with:—

Protosulphate of iron	20 grains
Acetic acid, glacial...	15 minims
Aqua dis.	1 ounce

Pour over the plate, and when it flows freely over the plate, add a few drops nitrate of silver solution. The image now begins to appear rapidly. When fully out, wash and fix as usual; it can now be intensified by any of the usual processes. It is important to wash the plate before developing, or the solution would not flow freely, but I think this is best done after exposure, by so doing, I have found the plate much more sensitive. I have also produced good pictures with albumen, gelatine, &c., treated in the same way. I have also succeeded in getting pictures with other metallic salts, but I did not find the results sufficiently encouraging to proceed in these experiments. I have sent you a specimen taken by this process, for your inspection, I know it is anything but perfect, it is just sufficient to show the possibility of another process. The picture No. 2, was taken with iodized spirit varnish, and nitrate of silver bath, but without the use of collodion. This specimen was taken more than two years since. Apologizing for thus taking up your valuable space, yours truly, Edward Smith.

8, *Old Bond Street, Bath, May* 7, 1861.

PHOTOGRAPHY AND THE EXHIBITION OF 1862.

Sir,—You appear to intimate, in your last number, that the photographs to be exhibited in the great International of 1862, will be classed in the section *mechanics!*

Should such be the case, I, for one, shall certainly decline to exhibit at all, and as I find that feeling is pretty generally entertained, the foreigners may very possibly have an opportunity of walking over the course without being pitted against some of our best men.

We have had ere now sharp internicine contentions about the nomenclature of the "art" or "science" of photography, which it would appear we should have fared better to have left balancing, like Mahomet's coffin, between these niceties of discrimination; or to have quietly contented ourselves with either of these king Logs, than to have been unceremoniously bundled out into "mechanics." I hope that the council of the International may see fit to revise this arrangement. I am, sir, yours,

"A Brother Chip," but no Carpenter.

Talk in the Studio.

Photographs of Eminent Men.—We have received from Mr. Mayall the first of a monthly series of portraits of eminent men which he is about to issue. The portrait before us is that of Lord Derby, and is an exquisite specimen of photography as well as a fine work of art. It is in many respects, in our opinion, incomparably the best of the numerous illustrious photographic portraits which have from time to time been issued. The lighting and general arrangement of accessories tends to produce very fine chiaroscuro, whilst the delicacy and perfect modelling of the features and head generally leaves nothing to be desired. Lord Brougham and others will, we understand, follow in succession.

Art Photography.—We have received from Mr. Rejlander two exceedingly fine art photographs. The first is a portrait of the artist himself dressed in Garibaldian costume, the effect of the red shirt being unmistakeable in the monochrome of the photograph. The features and general effect of the head very much resemble the portraits of the Italian hero; but the expression is more that of the refined and imaginative artist than the soldier. It entirely satisfies us as to what a portrait of Rejlander should be, and is consequently placed amongst the most cherished gems of our portfolio. The other is entitled "The Evening Sun," and represents a partially draped female figure with hand shading the eyes gazing towards the horizon at the declining luminary. The lines of the figure are very fine, and the folds of the drapery quite statuesque. The whole picture is full of poetry.

Photography for Book Illustration.—We always notice with pleasure the progressive advance in the use of photographs for book illustration. Unfortunately it has not unfrequently happened that when prints have had to be rapidly multiplied, they have been of such a character as to afford very little encouragement to those most concerned in the matter, commercially. A signal exception to this has, however, just come under our notice. A cheap edition, just issued, of Wilkie Collins' powerful novel, the "Woman in White," is embellished with a photographic portrait of the author, The photograph is by Messrs. Cundall and Downes, and reflects credit at once on the art and artists. Several from which have seen from different negatives, although varying in character, are all good. The head is one, which from the impress of character, at once powerful and imaginative, will satisfy the reader as well becoming their notions of the author of one of the most exciting novels of the day.

Copyright in Works of Fine Art.—The Attorney-General's new Bill for Amendment of Copyright in Works of Fine Art, was read a second time on Monday night, and ordered to be committed on Thursday. Some discussion arose on various points of detail, but no exception was taken to any point which would in any material degree affect photographers.

Photographic Studio Burnt.—The extensive establishment of Mr. Steel, photographer, was destroyed, a few days ago by fire. The gallery, laboratory, and printing rooms were all burnt, together with upwards of a thousand negatives. The fire originated in a neighbouring building. Mr. Steel was, unfortunately, not insured.

Art Treasures.—The *Athenæum* referring to the recent art purchases in Italy for the South Kensington Museum, refers to the value of photography as an aid in popularising art. The Campagna acquisitions consist of marbles and torra-cottas, statues, bas-reliefs, groups, &c., almost entirely of the great epoch of the Revival of Art, the Italian "*quattro-cento*." There is no doubt that the novelty alone, in this country, of original works of such world-renowned artists as Michael Angelo, Donatello, Ghiberti, Verocchio, Jacopo della Guercia, Rosellino, Desiderio di Settignano. &c., will excite at least, the curiosity of the general public, whilst artists and connoisseurs are likely to be impatient to see and judge for themselves of their merit and importance; it is, therefore, tantalizing to have to await the slow progress of bricks and mortar. The delay. however, appears unavoidable, as for a long time there has been no space at command at Kensington for the exhibition of previous acquisitions of a similar nature. The Science and Art Department are, however, doing their best to atone for the delay in causing the collection to be reproduced by means of photography, so that the public will at least be able, very shortly, to form an estimate of it, through the medium of that invaluable handmaid to Art.

To Correspondents.

U. A.—The name of the elementary works on chemistry is Legion. "Wilson's Chemistry," published in "Chambers' Educational Course," is a good one for beginners. 1. The names you mention are not all makers of lenses, some are dealers; those of No. 2 we use ourselves, and prefer to any we have met with. They possess the characteristic you require. 2. Chloride of gold should be neutralized with bicarbonate of soda, adding a little at a time, and carefully testing with litmus paper. In our own practice we simply neutralise with bicarbonate, and often use the solution so without the addition of any other salt of soda. 3. Where grains of acetic acid are accidentally given in a formula, minims are meant. 4. We prefer the use of oxide of silver for neutralizing a bath. 5. If you find kaolin satisfactory in decolourizing the bath, you have no object in change. We use it ourselves. 6. Your silver probably contains some impurity. See discussion at last meeting of the North London Society. 7. We have tinted paper photographs successfully with Newman's powder colours. The majority of the back numbers of the News are in print, and you can obtain them direct from the office by addressing the publisher.

D. Hornby.—We cannot direct you to any one work giving instructions for the manufacture of electrical and chemical apparatus. Faraday's "Chemical Manipulations" is, we believe, out of print. Greville Williams' "Handbook of Chemical Manipulations" contains much of the information you require. "The Boy's Play-book of Science," although possessing a somewhat juvenile title, is full of valuable hints on construction of apparatus.

T. P. E.—It is quite impossible for us to estimate the probable amount of silver in your waste solutions, or the amount of liver of sulphur necessary to precipitate it, as it depends on circumstances we have no means of knowing. Take a quart of the solution and test carefully the quantity of liver of sulphur necessary to be added to precipitate all the silver it contains, you will easily see when a black precipitate no longer falls. You will from that be able to estimate the amount require to precipitate the whole in your tank.

W. S. B.—The deposit to which you refer is caused by too rapid reduction of the free nitrate on the surface. A little nitric acid in the bath will remedy it without at all injuring the bath for positives. We have no faith in the especial value of secret dodges and formulæ. The formulæ you use ought with careful management to give very good tones. Perhaps the most silvery tones are produced by the protonitrate developer. Good results are generally due to a number of causes—chemicals all in good order, lighting judicious, manipulation careful, in fact, in the general harmony of the whole of the operations—not in tricks, secrets, and dodges. Bisulphide of carbon can be had of the chemists, the price will depend on the quantities in which you purchase. It is an active solvent of gutta-percha, india-rubber, &c. It is also used in optical experiments for certain purposes where its especial refractive powers are valuable.

S. F.—Your negatives are very far indeed from being perfect; but it is difficult to state the cause. They are very much under-exposed, and the collodion appears in very bad condition. Try adding half a grain of bromide of cadmium to each ounce of collodion; let it settle well, so as to avoid using it when turbid; filter your bath, avoid dust, and work carefully. Let us know your further results. The formulæ used appear all right enough.

James Forster.—A strong silver bath, say 40 grains to the ounce, acidified with nitric acid, and a protonitrate developer, give the whitest positives; but the application of a spirit varnish generally deteriorates the beauty of a glass positive, as indeed do all heavy-bodied varnishes. Try the varnish sold by Messrs. Squire as Alabastrine Varnish; it will not lower the brilliancy or whiteness of your picture at all. The specimen of intensifying you enclose illustrates the value of the process.

R. Gordon.—If you forward your address we will endeavour to advise you by letter: but cannot do so here.

Z. B.—We cannot recommend you to use any toning bath in which the gold and hypo are mixed. It may give fine looking results, but the risk of fading will be great. Use the alkaline gold toning process.

F. M. L.—The postage is a penny as in England. The subscription for the year is, therefore, 17s. 4d.

Economy.—Liver of sulphur and polysulphide of potassium are the same articles, and the smell is as disagreeable as you describe. The price you name is what would probably be charged for an ounce. It would be cheaper by the pound.

An Unfortunate.—There are a variety of methods of removing fixed stoppers from bottles depending on the fixing cause. Allow a few drops of water to permeate if possible between the stopper. Tap the stopper smartly but gently with a piece of wood. Heat the neck of the bottle, either by a flame or by friction. Tie a piece of string round the stopper and endeavour to jerk it out. Some of these means will probably succeed. We fear the silver stains in the table cloth, if they were not removed at once, will be difficult to remedy, cyanide of potassium will be most likely to effect the removal as far as possible. The treatment you propose for your silver bath is right.

F. E. G.—We will mark the pictures as you desire, so that we need not enter into the subject here.

H. B. Y.—Your method of proceeding was quite right, but from the results you describe we fear the pyroxyline is bad, from having been made a very low temperature, which would cause the thick glutinous effect you describe. You may possibly remedy the evil by adding ether until the collodion is sufficiently limped; but we fear it will never be good. The proportions we gave, if the cotton had been reasonably good, would have given you the proper consistency. Mr. Hardwick's Chemistry is the best for your purpose.

Y. S.—Your prints are deplorable. The negatives can have no intensity. Get better negatives more vigorously defined, and use a silver bath of at least 60 grains to the ounce, and your results will be more satisfactory.

R. Stephens.—We will write to you.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 141.—*May* 17, 1861.

RAPID DRY PROCESS.

We referred a few weeks ago to some prints we had received from the Rev. J. Lawson Sisson, described as from negatives by a very rapid dry process. We have since received from Mr. Sisson full particulars of his process, with permission to publish them; one condition only being attached to the permission. The condition was that we would ourselves fully try the process, so as to receive the fullest assurance of its value, prior to any publication of the details.

We have made some of the preservative preparation, and prepared a few plates, the results of which fully confirm Mr. Sisson's statements as to rapidity. An exposure of about fifteen seconds in a dull light, with Dallmeyer's Stereo lenses, and a three-eighth stop was sufficient. In a feeble sunlight we gave five seconds exposure, with the same lenses and a half-inch stop, which appeared quite sufficient. To afford a comparative idea of the amount of sensitiveness, we tried a tannin plate under precisely the same circumstances as to light, lens, stop, &c.; to this we gave an exposure of seventy-five seconds. The results in the two plates were very similar as regards exposure and general qualities. So far as this single experiment would indicate, the new process is fifteen times more sensitive than the tannin process. We must not omit to state the fact, however, that the rapid plate was developed with iron, whilst the tannin plate was, of course, developed with pyrogallic acid.

The preparation of the plates is very simple and easy, and the development rapid and clean. We hope shortly to try some more complete and comparative experiments, and also to receive the report of the experiments of a few skilled friends in dry photography, to whom we have supplied some of the preservative for trial. We shall then lay full particulars before our readers.

THE AMATEUR'S PHOTOGRAPHIC ASSOCIATION.

We call the attention of our readers to a prospectus which accompanies the present number of the News* of a projected Association having for its object the interchange and publication of the productions of amateur photographers. To become a member, it is necessary to send six or more good negatives during the year for publication, and subscribe a guinea. In return for this each member is to receive two guineas' worth of prints, estimated on a scale determined by the association; members will also have the privilege of being supplied with any additional copies of the prints published by the association at half the publishing price; and they will also receive one-half of the profits of any additional copies from their negatives which the publishers may sell.

In addition to these arrangements for membership, provision is made for admitting *subscribers* into certain of the privileges of the association without becoming members. Subscribers are exempt from the obligation to contribute negatives, an annual subscription of one guinea entitling them to a selection from the photographs of the association to the amount of their subscription, and to additional copies at three-fourths of the publishing price.

Four prizes will be awarded during the year for the best negatives forwarded: the prizes to consist of gold medals, of the value respectively of twelve, seven, five, and three guineas.

These and a few minor features constitute the chief aims of the association. The project is ingenious, and many of its objects are desirable; but we must confess that we do not look upon the probability of its successful issue with anything like enthusiasm. We see more difficulties in the working of such an association than are probably anticipated.

It is stated in the prospectus that this will become an "exchange club" of the most comprehensive kind. Now we have had some experience in the working of an exchange club, based on very simple and self-working principles. As a whole, the stereoscopic exchange club, established and worked out in connection with this journal, has been decidedly successful and satisfactory; but it has been because it has been self-working, involving little risk, and containing within itself its own corrective elements. Those who were dissatisfied with one exchange need not repeat it with the same member; had the amount at stake been heavier, we believe that dissatisfaction must frequently have arisen. The productions of different amateurs are necessarily so unequal, in a value which cannot be measured by the number of superficial inches of paper covered, that where such a standard is adopted in estimating their exchange value, disappointment must frequently ensue. If it be the duty of the committee to select or reject negatives for publication, their task, if executed with justice to all, will be anything but an enviable one; and however judiciously conducted must often issue in offence and annoyance.

There are some other details in the prospectus which are open to stricture: but as our object is not to throw cold water upon the scheme, but rather to point out some of the difficulties which will have to be met, we will not comment further on the matter at present. The committee include the names of some eminent amateurs, whose countenance will claim consideration for the association. We shall refer to the matter again shortly.

* We ascertain at the last moment, after the "formes" are "made up," that the prospectus will not be ready for issue in our present number, but will appear in our next.—Ed.

STAINS AND STREAKS IN THE NEGATIVE.

It is an unfortunate fact that the above heading is one which will at once interest a very large proportion of photographers; as there are few, however successful or eminent, who are entirely exempt from such troubles. At the last meeting of the Photographic Society, Mr. Thomas read a long and elaborate paper, a condensation of which will be found in another page, entitled "How to prevent stains and streaks in the negative." Mr. Thomas refers all these evils, or at least nine-tenths of them, to one cause, too much light in the dark room. Some of our readers will be disposed to smile at such a solution of their difficulties. That excess of light, or indeed *any actinic* light, in a dark room is an evil here can be no doubt, but that a cause, adequate at most according to Mr. Thomas's own showing, to the production of a certain kind of streak under certain circumstances, should be set down as the all but universal cause of all kinds of streaks and of stains besides, is, we think, to young and inexperienced photographers at least, a dangerous and mischievous doctrine.

The illustrations intended to confirm this notion, and to show how streaks might be present on the background and not on the figure, were most singular. Mr. Thomas laboured most patiently and most assiduously to prove what, we will venture to say, never entered into the mind of a gentleman present ever to doubt, namely, that the continued action of light would destroy a faint image already impressed on the collodion film, and announced the discovery of that fact as something unexpected and startling. Why, is not every photographic portraitist aware that the delicate detail and minor folds of light drapery are obliterated by the continued action of light? Do not all old Daguerreotypists remember the practice of covering a gentleman's shirt breast with a piece of black cloth for the first half of the sitting, just snatching it away towards the end, in order to prevent the white shirt from being "burnt out," as was the expressive phrase used? Do not all landscape photographers know, to their cost, that the faint impressions of clouds received certainly enough at the commencement of exposure, are quite obliterated by the effect of the prolonged exposure to the sky, which the landscape demands? And do not all these and a hundred other familiar illustrations simply indicate the fact, which Mr. Thomas's elaborate detail of experiments and the four negatives produced, were to demonstrate? But when this is admitted it goes but a very short way, that we can see, to prove that the presence of actinic light in the dark room is such a universal cause of stains.

We are disposed to affirm, moreover, that too little yellow light is quite as likely, in many instances, to be a prolific cause of stains, especially in developing. Mr. Thomas doubted the possibility of obtaining yellow or orange glass which would not admit the actinic rays, and it is quite certain the mere colour of the glass cannot be taken as a safe guide without actual testing. But that it can be obtained is not less certain. We have worked for months in a room lighted with about four superficial feet of yellow glass without ever experiencing the slightest difficulty. We have before us at this moment three samples of yellow glass, and we have also a print on paper which shows the amount of resistance to the actinic ray of each, the glass and the specimen having been forwarded to us by an able amateur photographer. To test the samples, he mounted them in a frame of wood side by side, and placing an excited collodion plate underneath, exposed it to the northern sky for thirty seconds. The result was that the light admitted by two of the samples caused a reduction as dense as the high lights of a good negative, whilst the third, under the same circumstances, did not suffer sufficient light to pass to produce even the slightest fogging. The two first samples were apparently of deep brownish orange, whilst the third was much lighter in colour, and was moreover the cheapest article. The two first were "flashed" or stained glass, the third pot-metal.

Without entering further into this subject here, we may call the attention of our readers to an interesting detail of the experiments of Mr. Crookes, referred to by Mr. Malone at the meeting. They will be found as communicated to us by Mr. Crookes in our article "Scientific Gossip" in the present number.

We are sorry we cannot endorse Mr. Thomas's opinion that the preparation of photographic chemicals is so much improved, as to render the excited film so much more susceptible than it was a few years ago, to the action of light. We are not of those who croak that photography has made no progress. We believe that it has progressed, and that many things are much better understood than they used to be. But we cannot forget that Count de Montizon and others took instantaneous pictures half a dozen years ago or more; nor can we ignore the fact that never were complaints more rife than at the present moment, and that amongst first-class men, of the difficulty of procuring really pure and reliable nitrate of silver, and that they can seldom procure, even from the best makers, two batches of collodion alike.

The causes of stains are very numerous, and perhaps none more frequent than the use of imperfect or imperfectly cleaned glasses. The cause indicated by Mr. Thomas will sometimes doubtless cause streaks, and more frequently fog; but not, that we can see, stains. Organic matter in the bath; or the use of a simply iodized collodion when newly mixed are prolific causes of streaks and stains. A very frequent cause of stains is imperfect manipulation in the development; the plate not being covered with an even sweep of the developer, or the developer flowing back from the edges in greasy lines. A very common and often unsuspected source of streaks is the presence of scum on the surface of the bath, which, if the room be very dark, is not observed. There are other causes of streaks and stains, but these are the chief. We mention them that the inexperienced photographer may see the necessity of carefully overhauling the whole of his operations when he meets with these difficulties; and not fancy that by making his dark room so dark that he cannot move in it without upsetting something, he is forthwith to rid himself of further trouble in this respect.

Nevertheless, too much stress cannot be laid on the importance of excluding all actinic light from the dark room. The more perfect the working condition of the chemicals the more dangerous will necessarily be every stray beam of white light. On this subject Mr. Thomas's concluding remarks are interesting, and may be read with profit.

Scientific Gossip.

The important photographic chemical, hyposulphite of soda, is gradually being applied to other uses. It promises now to become a valuable agent in chemical analysis, its great disposition to form easily soluble double salts enabling the chemist to separate similarly allied elements with considerable facility. Diehl has now found that it dissolves sulphate of lime with great ease, and has proposed it as a means of separating this sulphate from the insoluble sulphate of baryta. When alcohol is added to the solution of sulphate of lime in hyposulphite of soda, the double salt separates out in the form of a heavy oily fluid, congealing into white crystalline needles, and mixed with hyposulphite of soda. The hyposulphite also exerts remarkable solvent powers on the ferro and ferri-cyanides of copper, lead, silver, and mercury, while it will not touch the corresponding compounds of zinc, manganese, cobalt, nickel, cadmium, and tin. It is much to be desired that these curious solvent powers of this salt were fully investigated; besides the advantage which chemistry would derive from a knowledge of such reactions, photography could not but be benefited by any researches which would throw light upon the obscure actions of one of her most valuable agents.

Mr. King's experiments on the loss which light experiences by its passage through glass plates of different qualities, an account of which we gave in our "Scientific Gossip" for Jan. 11, have attracted considerable attention, both in this country and in America. We know of more than one artist who has been much benefited by the results which we gave, in the construction of a glass room, and they will be pleased to hear the results of some further experiments on the same subject, upon which Mr. Storer has lately been occupied, in consequence of Mr. King's researches. Mr. Storer employed, instead of lamp shades, flat sheets of glass (ordinary window panes) six inches wide by eight inches high. These were fitted to a rack of blackened wire, which was fastened to the photometer bar (100 inches long) at a distance of three feet from the gas light. It did not appear that the distance from the source of light at which the glass screen was placed had any appreciable influence upon the amount of light transmitted by it, at all events no such influence could be detected in a number of experiments made purposely to test this question. The gas employed was prepared from a good coking coal expressly for these experiments, and was contained in a special gas-holder. Its illuminating power, when consumed from an argand burner at the rate of five cubic feet per hour—as in the following experiments—was equal to 16 candles, consuming 120 grains of spermaceti per hour. The experiments were made in a blackened chamber with a Bunsen's photometer, every precaution being taken to ensure accuracy. It may also be mentioned that none of the measurements (of the distances of the photometer from the standard candle) obtained by actual experiment were calculated, *i. e.* reduced to their equivalents in candles, until the whole series of experiments was completed, and that no comparison of the results among themselves, or with those of Mr. King, was made until each number of the table had been calculated as it stands below. Whatever the experiments may be worth therefore, they have at least the merit of being entirely independent, and wholly unbiassed. The amount of light passing through the glass plates, was in all cases taken at 100, and it was found that English pale, one-third of an inch thick, obstructed 6·15 per cent.; Crystal plate, one-eighth of an inch thick, obstructed 8·61, per cent.; English crown the same thickness, 13·08, per cent.; Double English window glass the same thickness, 9·39 per cent. Double German the same thickness, 13 per cent.; whilst the same glass half the thickness, obstructed only 4·27 per cent. When glass is ground, a vast increase in its opacity to light is the result; three specimens of the above glasses rising in this respect to an obstructive power of 62·34, 65·75, 62·74, per cent. A piece of orange-coloured window glass, such as photographers use for their dark rooms, the sixteenth of an inch thick, was found to have an obstructive power over 34·48 per cent of the rays. Purple glass the eighth of an inch thick, absorbed 85·11 per cent. Ruby glass the sixteenth of an inch thick, 89·62. Green glass the same thickness, 81·97; and a porcelain transparency the same thickness, as much as 97·68 per cent. of the incident rays. These numbers vary somewhat from those given by Mr. King; this may be explained by the fact that the window glass used by Mr. Storer was more coarsely ground than the lamp shades used by Mr. King. There can, however, be no doubt that the numbers given above express as accurately as the circumstances of the case will admit, the actual diminution of the amount of light falling for example upon the pages of a book held near to its source, which would be occasioned by the interposition of the shades above enumerated. The enormous resistance to the passage of light which is offered by ground glass, is certainly worthy the attention of those using it for glazing the whole or any part of their glass rooms; whilst the comparatively small amount of light (34·48 p. c.) obstructed by orange glass is also worth consideration.

Some very erroneous ideas having been expressed at the last meeting of the Photographic Society relative to the opacity of yellow glass to the chemical rays of light, and Mr. Malone having alluded on more than one occasion to Mr. Crookes' experiments on this subject, we have thought that some notes of experiments, which the latter gentleman made on the occasions referred to, would be of interest. The experiments were tried with a powerful spectrum camera, which was so arranged that an image of the solar spectrum, with Frauenhofer's lines crossing it, could be projected upon various sensitive surfaces, and at the same time be subjected to the absorptive action of screens of different kinds. This instrument was employed for the purpose of ascertaining the best kind of glass for the window of a photographic laboratory; one which should admit abundance of light, and still filter off, as it were, all chemically acting rays. Usually yellow calico was employed for this purpose, but Mr. Crookes found by means of his instrument that this was a most imperfect and unsafe material for such a purpose. One thickness, it is well known, allows white light to pass readily. Consequently, an increase in the number of folds merely diminishes the amount of transmitted white light, and in the same degree obstructs the illuminating yellow light. A great many pieces of glass were examined with this instrument with a view to find out some which would perfectly obstruct the photographic rays. The method of experiment was very simple. Mr. Crookes first took a photograph of the spectrum and found out the fixed line in it which acted as a limit to the chemical rays. For iodide of silver in collodion (or in any other combination (the action suddenly ceased at a point below), *i. e.*, nearer the red than) the line G, equal to one-sixth the space between the lines G and H. All the rays above (*i. e.*, nearer the violet than) that point of the spectrum (which occurs at about the boundary line of the blue and indigo) being found to affect the collodion plate strongly, whilst the rays below it were absolutely without action. Iodide of silver was, therefore, found to be *insensitive* to blue light, contrary to the usual opinion. Bromide of silver was in the same way found to be sensitive to all the rays above the group of lines *b* (between E and F in the middle of the green) and absolutely insensible to the rays below.

The problem to be solved was, therefore, very simple. Mr. Crookes had only to obtain a good solar spectrum in the field of the telescope, and having focussed the fixed line *b*, to interpose in the path of the coloured rays as many pieces of coloured glass as he could procure. All glasses which were opaque to the rays above the line *b* could safely be used for illuminating the photographic room. Amongst the most perfect of the glasses which were found in this manner suitable was a rather common kind of a deep orange colour. It was perfectly opaque to rays above Frauenhofer's line E, from the green upwards, but transmitted the lower luminous rays with facility. Mr. Crookes, therefore, employed this glass to glaze the window of his photographic laboratory, and, although, during part of the morning the sun used to shine directly through it on to the uncovered glass bath in which collodion and other plates were being excited, not a single failure could ever be traced to this cause, and whilst, in point of security, this orange glass was at least equal to four or five thicknesses of yellow calico, it was incomparably more pleasant to work by, as when the sun was shining the darkest corners of the room were illuminated as if by daylight.

DRY PHOTOGRAPAY IN THE DARK-ROOM AND FIELD.

BY H. NICHOLS.

As the numerous modifications that are constantly made tend to bother the dry-plate photographer, from being based on conclusions hastily made, and without that impartial comparative experimenting necessary to render any process simple and certain in the hands of all, with any pretensions as photographers, I beg to place before you the method which in my hands, and those gentlemen who use it, is simple and certain in its results, giving clean, sharp, and vigorous negatives, without stains or marking of any description; very sensitive, seldom requiring more than one minute exposure in mid-winter, with a lens of 5-inch focus; good keeping properties, the plates used fifteen months after preparation yielding equal results as when first prepared.

I must now conduct you into the laboratory, I would first remark, that the statement frequently made that any collodion giving a good wet negative will do, is in my opinion an error. Ignoring then all mixture of contractile collodion that has become powdery by age, or caustic alkalis,—such films when sensitized generally showing to the unassisted eye watery marble stains, soon becoming partially or wholly insensitive in light, and rapidly decomposing—the following formula I use with success:—

Soluble Cotton.

Pure nitrate of potash, coarsely powdered	20 drachms
Distilled water	1 ,,
Sulphuric acid (s. g. 1840) ...	24 ,,
Clean carded cotton	100 grains

I use a tall percipitate glass, kneading the cotton occasionally with glass spatula, and keeping it covered with a glass plate when at rest for twenty minutes, then washing rapidly in an earthenware cullender under a tap with a powerful stream of water, which soon removes all traces of acid and bisulphate of potash. Then pull out the fibres and dry in the open air.

Plain Collodion.

Sulphuric ether, (free from acetic ether	2 ounces
Alcohol (s. g. 1·815)	2 ounces
Soluble cotton	28 grains

Iodizer.

Iodide of ammonia	24 grains
Iodide of zinc	12 „
Bromide of ammonia	12 „
Alcohol (s. g. 1·815)	10 drachms

To seven drachms of plain collodion add one drachm of the iodizer.

This iodized collodion will flow freely without ripples, very porous, giving a rich film, adhering well to the glass, and will bear any amount of washing, if ordinary care is taken, will be fit for use in two days, and remains in good working condition for many months.

The Nitrate Bath.

Nitrate silver crystals	45 grains
Distilled water	1 ounce

Add to a 20-ounce bath, 4 drops iodizing solution, and 6 drops of glacial acetic acid.

Filter the bath solution with care, using good paper. I always test my filtering paper, for carbonate and hyposulphate of soda; for many of the papers lately in the market I have found to contain from 2 to 5 per cent. of those articles so useful for other purposes, but so detrimental here. I use a yellow glass bath in preference, or of gutta percha unvarnished; for as the bath solution acquires alcohol and ether, the gums of the varnish are dissolved, and fix themselves on the collodion surface, mostly in patches, sometimes all over, causing difficult development in *recent plates;* in six or eight weeks after preparation the patches become visible, although to view the back of the plate it has all the appearance of being good. After coating and sensitizing the plate in the usual way, remove into another bath of the same description containing distilled water, placing the plate the same way on the dipper, and dipping in the same direction as before, leaving it in while another is being coated and placed in the former bath; when it is to be placed on a level stand, and washed with an unlimited supply of ordinary water that has been well boiled; drain the plate on clean new filter paper, then coat with the albumen solution:—

Albumen	1 ounce
Distilled water	3 ounces
Liq. ammonia (880)	1 drachm

Shake well to a froth in a bottle; when subsided, and perfectly clear, filter through muslin into a *clean dry* bottle, this will keep good a year or more. Pour enough on the end of the plate to cover it well, letting it flow as regular in a wave as possible to the opposite end, then over in every direction well up to the edges. Pour off over the plate with water while the plate is changed from the sensitizing to the water bath, and another coated and placed in the nitrate bath. Having three plates in hand, return to the first and finally wash as before: hot water (180° Fahrenheit) may be used, if increased sensitiveness is required, without injury; above that heat difficulty in development I find the result.

Proceed to dry: first drain the plate on a pad of new filtering paper, wipe the back clean and dry, and place it about one inch away from a bottle or jar of *hot* water, film side to the source of heat, slightly inclined away at top, resting against something else, with three or four thicknesses of bibulous paper under all. When perfectly dry, my way of storing the plates is simply to place a piece of clean bibulous paper between each, film side up, in pine boxes; as long as they are kept dry they will be good, and as sensitive as when first prepared.

The next movement is to take the field. It is necessary to know how long to expose, and this rarely costs me much trouble. There may be plenty of methods better than mine, no doubt, only I don't know them. My little instrument never having deceived me, I'll describe it; it consists of a little box with a shutter fitted like a dark slide, about 2 inches long, 1¼ wide, and ⅝ths of an inch thick, which I carry in my waistcoat pocket. On the inside of the bottom of the box a piece of card, coloured purple-brown, is placed, the corresponding shade to that acquired by the sensitized paper employed. A slip of sensitized paper about half an inch wide is laid lengthways down the middle. To use it, open the shutter about the eighth of an inch, and note the time of coloration to the card.

The following formula, I find, requires about eight times longer than the plates, using *papier le Rive.* To salt the paper.

Chloride of sodium	... 8 grains
Bromide of potassium ...	... 8 „
Water	... 1 ounce

Immerse the paper three to four minutes. Pin up to dry.

Sensitizing Bath.

Nitrate silver crystals ...	... 35 grains
Lemon juice	... 2 drops

Cover a glass plate, a little longer than the paper, with the bath solution, place the salted paper in contact for three minutes, using fresh solution for each paper, never return to the stock solution, as that would alter the time of coloration, and lead to error.

One strip of the sensitized paper lasts twelve exposures, by opening the shutter about one-eighth of an inch each time; although the use of this is only occasional, I always carry it ready for use when light appears doubtful. It is called into actual service in the following way:—suppose twenty plates are prepared, place one in the dark slide, having focussed your object, expose the photometer by opening the shutter as described, noting the time of colouration; supposing that in four minutes the depth is produced, one-eighth of which is the calculated time, then expose one-half of the plate thirty seconds, the other half sixty seconds, develop the plate, using the developer hereafter mentioned; should thirty seconds be under and sixty seconds over, expose about forty-five seconds or thereabouts.

Another useful little thing, not to be forgotten is a view meter, which often saves a great deal of trouble and annoyance. It is very easily made and managed, which will be better described at another time. After the journey's end, develop the plates at leisure. Developing solution—

Pyrogallic acid	... 8 grs.
Citric acid	... 4 „
Distilled water	... 6 oz.

First moisten the surface of the plate, add to each drachm of developer one drop of a twenty-grain solution of nitrate of silver—five to ten minutes generally completes development. Over-exposed plates may be successfully treated by saturated solution of gallic acid; with added to each ounce, one drop of silver solution (bear in mind, that half the plates are spoiled by adding too much silver to the developer); wash well, fix with saturated solution of hypo, another good washing, dry it before the fire, and varnish. Gum benzoin dissolved in spirit, properly made, will never crack under any circumstances a negative is required to be used.

A few remarks on the appearance of the dried film may be useful:—They are generally opaque and lustreless, very sensitive, quickly developing—a glassy surface is generally less sensitive, requiring longer time to develop. A film having a varnished appearance generally develops with difficulty, giving a soot and whitewash picture.

Remarks on applying the albumen.—This solution, by its passage over the plate, forces out the water before it, which, with a little practice, you can force over the end, or it can be well effected by a well bath. For large plates I find it best, as the albumen can be used in succession—supposing one oz. be required to cover one plate, then for twelve plates use twelve ounces, or as long as there is sufficient to cover the plates; for if it has been properly washed the albumen remains clear, and its only purpose, as far as I can find, is to keep the pores of the collodion open, as there are many other substances having the same effect, or even better.

GROUPING AND ARTISTIC EXPRESSION.

BY L. M. DORNBACH, S.B.*

The first and most important requirement in taking a photographic picture is a faithful representation of the outlines and characteristics of the original, by which we obtain, at the same time, the most desirable and harmonious picture, satisfying the eye, and the ideal conception of the mind.

That which is very easy for the painter in the production of agreeable portraits—agreeable in conception, position, surroundings, &c.—becomes almost an insurmountable obstacle to the photographer, notwithstanding he may be provided with the best instruments and the most reliable chemicals, individual skill and the most faithful representation of the original; and, to give to the whole a spiritual or life-like appearance, belongs only to the domain of the best of painters.

The question presents itself, where the source of failure lies in accomplishing all the requirements which a perfect photograph demands? The answer is an easy one; in the want of artistic or picturesque perception and performance; or, in other words, the difficulty in arranging the subject to be taken so as to present the best possible appearance in the picture. There is some difficulty in giving practical hints, and defining the principles involved, to produce results that shall possess all the requirements that are possible in every particular case.

Viewed from a purely professional stand-point, all photographic pictures deprived of, or wanting in, artistical and picturesque properties, though they may not receive the most direct appreciation, are not the most admired, even if they are more beautiful than the originals. Concerning the want of delineation in detail, we will present those points which must be observed in artistic relations.

In grouping we have the following divisions:—First, the position of a single person; second, the grouping of a number of persons; and third, the arrangement of surrounding objects.

The first point—the position of a single person—presents the least difficulty; nor is it essential that the photographer should be acquainted with the character, the disposition, and standing of the person, a circumstance, it is true, that is seldom called into requisition. Still, in order that he may be somewhat familiar with the character of his subject, the practical photographer will take advantage of the time and opportunity in preparing to take a picture, to recognise all the salient points of character, by entering into a conversation upon general or scientific topics.

We insist upon this the much more, since it has been customary to represent all persons alike in their pictures; a sort of stereotyped attitude—a small table covered with figured cloth supporting a book. But all are not alike in their tastes, and an active business man, or a mechanic, seems out of place when taken as a literary man.

According to the result of these conditions the general harmony of the entire body, and the position to be taken, are to be determined. The age of the person whose photograph is to be taken may be considered in this place, and presents very little difficulty. The position is of much less importance when no external characteristics—costumes, robes, uniforms, &c.—require to be considered.

The first and most important general consideration is to associate whatever naturally belong together, and which are dependent upon the difference found in the human family. When the photographer is called upon to take a portrait of a single person, in a sitting position, the best rule to follow is to have the individual place himself in the chair and arrange himself naturally at his pleasure.

The just proportion, viewed from the particular relation of all the parts, must be preserved under all circumstances in the harmony, relief, immediately after the grace and beauty of composition—which should never be lost sight of—whether the person is standing or sitting. We must bear in mind, in this arrangement, that the method which succeeds best in giving a life-like expression in the general harmony corresponding in the position of the arms and hands of portraits, in which life can only be successfully deliniated, the inclination and *posé* of the head and breast, will be best for the expression of face and eyes.

By strictly following these rules, we give the person the position of a narrator, observer, thinker, &c., corresponding to the mental inclination of the individual, and consequently every case that presents itself will fall into its proper category unless the operator is very careless, and works without any taste, or is prevented by the presence of unavoidable disturbing causes.

But it must be remembered that in the application of these principles an exceptional case may arise where a picture cannot be taken by them, and above all things a stereotyped order must be avoided, a circumstance which enhances the value of every picture a hundred-fold.

In the arrangement of the individual parts of the body, the following general rules should be observed:

The head must be placed erect, within a perpendicular to the rest of the body, whether observed from before or from the side. If a front view is taken, a foreshortening of the forehead, nose, chin, &c., takes place, and the look, to which a proper direction is always to be given, is either squinting—which is never a desirable feature, being the most disagreeable of any—or, in case it is kept slightly sideways, when it is indistinct and lifeless.

For the same reasons the head should not be taken partly from behind, since, from the same foreshortening, the expression will be very tame, the eye will be small, and, what is more reprehensible, the portrait will show the nostrils too prominently. Besides, this last position gives the picture a very undesirable expression; it does not agree with the character of the person, and has little or no personality, and in every respect is a poor picture.

Thus again, let the position of the head be perfectly straight, but at the same time without constraint, and as easy and graceful as possible; it must still be kept in view that these are merely pictures of such subjects as make up the generality of persons, or, as we might call it, pictures of every-day people.

But this rule is not applicable to actors, painters, artists, speakers, &c., for here different positions must be called into play; an irregular and inclined position of the heads of portraits gives them a more characteristic expression, as well as more life and truth.

Still this is a matter of refined judgment and cultivated taste, which a skilful photographer should never be deficient in.

In connection with the position of the upper part of the body, the arrangement of the breast, arms, and hands, in relation to the position of the head and direction of the eyes, is next to be taken into consideration. The arms, hands, and breast must exactly coincide in harmony with the expression, which is introduced by the position of the head, from which it follows that they must be unconstrained, yet so situated that a proper character is thereby expressed and preserved.

An adjunct, consisting of a small table or stand of some description, is in most cases a desirable assistance in giving a finish to the picture. But this will be more fully treated of under a separate head—the surrounding objects of the tableau.

Stiffness, or want of ease, whether relating to the chest, arms, or hands, is under all circumstances to be avoided. The upper part of the body must, above all things, present a roundness and give an impression of comfortable ease. The chest is first placed in such a position, that the axis of the plane in which the shoulders lie shall not be parallel with the inclination of the head, which prevents the picture from appearing broad and disagreeably harsh.

The arms should never present parallel positions in any of their parts, but must either rest free and easy upon the lap, yet not carelessly so, or be placed in a position corresponding to the particular position of the hands, which must be so situated that they lie as near the body as possible, without resting upon the knees, nor be closed so as to make a caricature.

Not unfrequently, at least in portraits of men, it is desirable to conceal one of the hands, or at least in part, by placing them on the breast (concealed by coat or vest), or by passing a finger between two buttons of the clothing, in order that the arm may have a point of rest.

The next in order will evidently be the arrangement of the lower part of the body: this admits of very little application of any rules, with this provision, that the position of the feet must be perfectly natural and easy, and so placed as to ensure rest and security to the upper part of the body.

With a standing posture little is necessary to be done, and

* Abbreviated from *Humphrey's Journal*.

particularly in the arrangement of females, the excellence of the picture does not depend upon the particular position of the feet further than to obtain security and ease for the body, but is dependent more upon the faultless arrangement of the dress —the prevention of disagreeable folds. If the skirt hangs loose on the body, the folds of the dress will not indicate whether the person was sitting or standing. This, however, cannot be regarded as part of the domain of the photographer, yet it may be the source of poor pictures.

The operator will therefore, as far as practicable, see that the folds of dresses are properly arranged, and be particular that the position of the whole person, as well as individual parts, is properly represented.

From these outlines we may easily secure all that is desirable in a portrait: ease in posture, relief in outline, and beauty of composition, harmony in all parts, and—what is of the utmost importance in a good picture—the general impression of natural life and ease.

In our next article we will give the grouping of several persons, or the rules to be observed in forming groups.

HOW TO PREVENT STAINS AND STREAKS IN THE COLLODION NEGATIVE.

BY R. W. THOMAS.*

My object this evening is to place the subject of my paper in a practical light, by which light, I am happy to say, it is capable of being viewed; in doing this, I will also endeavour to answer an objection which will present itself in the course of this inquiry. Now let me take the subject and divide it into two heads, and then discuss these heads separately.

1st. The action of light in the camera.

2nd. The influence of light in the operating-room.

For my present purpose it will be enough to glance casually at these heads. First, the action of light in the camera. All things considered, is it not wonderful that we have a clear image in a latent state upon the highly sensitive surface of the collodion plate? Light passes equally into the darkened chamber through the full aperture of the lens; but at the focus of the lens it is also deposited, so to speak, in a ratio equal to the reflecting power of the surfaces of the objects to be copied, impressing the first atoms of the sensitive film in a degree equal, as before stated, to the amount of light projected from the bodies to be represented. Now it will be readily granted and very easily conceived how soon a disturbing influence may be brought about by the introduction of any false light in the chamber wherein this image is produced; but notwithstanding this incontrovertible fact, there are those who remain careless as to the manner of rendering the camera absolutely dark. I have said that the light given off from the objects to be copied impresses the first atoms of the sensitive film, and I firmly believe that the first atoms only are affected in the camera.

In furtherance of this proposition, let us imagine for a moment that a bundle of thin surfaces of any material sensitive to light be placed (say, for the better comprehension of the subject) at the slightest conceivable distance apart in the focus of the lens, the colour of each and all of the surfaces being antagonistic to the action of chemical rays (in other words, yellow, the colour of the iodide of silver in the film), and the homogeneity of the colour favoured by the circumstance that light is not passed absolutely through these atoms (that is to say, the back of the dark slide being closed, translucency of the supposed thin yellow surfaces is prevented). Now what will be the result (keeping this arrangement in view) of the action of light? Undoubtedly the image of the object to be copied will be deposited upon the first surface of the suppositious arrangement, and there receive a check. You will grant that the next surface must, if at all impressed, be so through the yellow medium of the first; and so, of necessity, the light parts with a portion of its actinism; and having thus passed through the two yellow surfaces, I doubt whether any other of the series would be effected. I have made use of this hypothetical arrangement of surfaces for the convenience of explanation only. To those conversant with chemical philosophy, the iodized collodion film, whether $\frac{1}{16}$th of an inch or 1 inch thick, would equally afford an exemplification of the theory advanced.

I now proceed to examine the action of light in the dark room. I think it will be allowed that the more sensitive a prepared plate is to objects in shadow, the more sensitive it will be to yellow light; and if a preparation could be made, capable of producing a landscape in the camera illumined by moonlight, I need hardly remark that it would be necessary (arguing in the abstract) to prepare this highly sensitive plate in total darkness and develop it under precisely similar circumstances. Such a high degree of sensitiveness would be very inconvenient, and has not yet been obtained; but such a discovery is within the bounds of probability, and the course to be pursued in order to obtain a clear image must, under such a condition of sensitiveness, be the one proposed.

Now let us for one moment take a retrospective view of the progress of the science of photography. There are those present who can remember well the time when the negative paper process was the only process employed for taking portraits; the sitting, under the most favourable circumstances of light and short-focus lens, was 60 seconds, but generally, I think, averaged 2 minutes. I will not diverge too much from my subject, for I like to keep to the text; but were it admissible in this paper, I could give some interesting historical facts concerning the earlier days of collodion. Well, what have we been doing all this time since the old paper negative process was set aside for the purposes of portraiture? The photographic chemists have been steadily advancing to perfection in the preparation of both collodion, nitrate of silver bath, and a few other less important chemicals, in order to obtain the maximum amount of sensitiveness, preserving at the same time other conditions necessary to the perfection of the result. On the other hand, let me ask what have photographers been doing all this time? Many of them have been treating these improved preparations in much the same way as the man who would take pictures by moonshine and neglect the precautions just laid down, necessary for the clearness of the image; in other words, photographers have been working in rooms with as much yellow light as was used in the old days of photography. Now I will endeavour to show the result of such a course. I will not suppose for a moment that any other than a neutral bath is being used. A plate is prepared and plunged into the nitrate of silver bath, and the door of the room closed; after a minute or so the plate is taken out and moved up and down, to equalize the action of the bath, and remove greasy lines caused by the contact of ether with water, these two not being at first perfectly miscible.

Now, at this stage all the damage is done; the so-called darkened room is by no means dark enough, the greasy lines are impressed more or less according to the intensity of the light prevailing at the time, and appear subsequently in the development as well marked as any other latent image that the lens is capable of producing. Let me ask you to call to mind the first part of my paper and its illustration. I introduced this illustration in order to prove my position at this stage of the argument; you will remember that I was at some pains to demonstrate that the image in the camera impressed the first atoms of the collodion film, and that this film, in its position in the camera, was not translucent, but opaque; hence the first atoms were impressed only; but the reverse of this takes place in the dark room; the prepared plate is always more or less transparent, and admits of light passing through it, according to the relative position of the plate, and the source of light; moreover, at this stage of its excitation it *may* be in a highly sensitive condition.

Now is the time for me to introduce the only objection that can be made to this theory, viz., how is it that I can get perfectly clean pictures with a particular preparation of collodion, and may be the same or a particular bath, and yet when I take this or that preparation I obtain greasy lines or stains? In reply to this objection, I say, in the first place, that this statement, if it be made, is only partially true, and if true the reason is evident. The most superficial observer must have been struck with the difference in the appearance of films of different kinds of collodion when immersed in the bath; some (even after a short immersion) becoming opaque, whilst whilst others remain translucent even after a prolonged immersion. I make use of this objection as the strongest proof of the soundness of my views. Is it not most clear that this very property of opacity arrests light passing through the film, and prevents the action traversing all the atoms of the mass in its entirety? Now I think I have shown the use of my first illustration. The fact is, the surface of this opaque film is (in the dark room) in precisely the same position as the first atom

* Read at the meeting of the London Photographic Society, May 7th, 1861. [We are compelled from its length to curtail this paper, but we give all that is important to its argument.—Ed.]

of the translucent film, placed vertically in the focus of the lens with an opaque body behind it, and clearly shows theoretically, what is proved to be true by experiment, that the stains are not produced in the camera, whether the film be opaque or translucent, provided due attention be paid to the quality of the yellow light in the dark room; but, on the other hand, the stains can be produced at will, and especially with a translucent film, if the light in the dark room is not of the proper quality or is too actinic. Herein we have the key to the whole position; the translucent film is more readily impressed by feeble light in the dark room, and this impression is rendered more permanent from the fact that light passes through the entirety of the atoms of the film in consequence of its translucency. I shall not again refer to this part of my subject, but will pass on to another phenomenon, which must have been to many a matter of astonishment,—I refer to the frequent occurrence of those streaks in the background of a portrait, and their absorption at the point of contact with the image in absolute focus; is not this an extraordinary fact? and, moreover, one worthy of close observation? I must confess that until I gave a great deal of attention to this subject, I was not only puzzled, but vexed at the want of a satisfactory answer. It was not satisfactory to my mind to be able to say I know how to produce and how to avoid these stains; I therefore set to work to find out some tangible reason and ground of explanation. The experiments I made appeared suggestive; I have the pleasure of handing round the results by way of illustration. Plate No. 1 exhibits the image of a circular disc of yellow tammy stuck to the centre of a piece of amber-coloured glass; this was supported vertically on a stand and a scratch made to indicate its position; a plate was prepared in the usual way, and a negative taken of the yellow disc; the exposure required was found to be three seconds. A second collodion plate was prepared, and exposed in the camera the same time, viz. three seconds, and the cap placed on the lens, an image of the same disc having been impressed; this time, however, the yellow glass with the disc was removed, and in its place a piece of white cardboard was substituted: recollect that the plate No. 2 is still in the camera. Having effected this exchange of objects, the cap of the lens is removed and an instantaneous exposure of the white card is impressed upon the latent image produced by the first exposure; the slide with the plate is then taken to the dark room and developed. Now, gentlemen, let me ask what would you expect to find,—the image of the yellow disc, the cardboard, or both? the result is that the image of the disc is scarcely perceptible, and, moreover, is not any more evident at any stage of the development than is here represented: I have ascertained this by stopping the development at various stages. Again, in the third experiment, reverse the order of exposure, that is, first impress the plate with an instantaneous exposure of the white cardboard, and then superimpose the image of the disc; in this case the result is the same, the image of the disc is scarcely visible; but let us proceed to find out whether it can be made visible. Plate No. 4 will show that this is possible; but in order to effect it, an exposure of 15 seconds is necessary, being five times the amount of exposure required under ordinary circumstances. Now I think that these experiments may be made somewhat instructive; they at any rate very clearly shew that the fainter impression becomes subservient to that more intense, and that the faint images of streaks produced in feeble light become shrouded or absorbed by the more powerful action of the image in focus.

Now, gentlemen, as supplementary to my paper, let me offer a few remarks. What is the amount and character of light which can be safely used in the dark room? In reply to this inquiry there is fortunately a very clear answer; let me state it. And first I wish to lay down as a rule, that with properly prepared collodion, no matter what the light out-of-doors be, the negative image, whether under-exposed, or just enough exposed, should more or less, on some portions, and generally of course on those parts in deepest shadow, show a bright positive surface. If therefore the surface is at all deadened with a short exposure, notwithstanding that a neutral bath be used, then I say there is too much light in the room: no better test can be had. Another guide is the behaviour of the developer. The solution of pyrogallic acid should remain bright brown for some time; too much light in the room will cause it to blacken, and in some cases throw down a loose black deposit at a very early stage of the development; I recommend every one to adopt the course I am now going to suggest. Darken the room entirely, so that no object be discernible; slits, crevices and holes will then be seen. Now let light into the room, passed through a piece of amber-coloured glass, covered closely on each side with a single thickness of yellow tammy. For the purpose of experiment, let this aperture of yellow light be as small as possible; under these inconvenient conditions of light, develope a picture, and note well its character; then find out by degrees how much larger the aperture of yellow light may be made, so that the beauty and purity of the picture be not less on comparison with the first result obtained almost in darkness, and which may be called the test plate. It will then be very soon ascertained how large the aperture of yellow light may be made with safety. Let it be, however, remembered that this experiment must be performed on a bright day, when the light is strongest upon the covered yellow glass. I do not believe that either yellow glass or dyed stuffs *alone* can be depended on; the perfection of a yellow light for photographic purposes will be found in a combination of these two substances. The number of superficial square inches of light passing through this medium must be regulated according to the position of the window through which the light passes; hence the necessity for these experiments, and the difficulty in laying down any fixed rules.

I assert plainly, that the truth of this paper lies in a sentence; you may thrust away from your minds every theory that has been advanced, bearing in mind the one statement only, that the principal cause of want of success in photography, and of streaks in the negative, is due to the introduction of too much light in the dark room.

OLD AND NEW INVENTIONS FOR PRESERVING PHOTOGRAPHS AND OTHER WORKS OF ART.

Mr. Harvey, the patentee of an exceedingly perfect portfolio, read a paper at the recent meeting of the Photographic Society under this title. His principal object was to show the importance of giving proper care to preserve works of art, which had cost much care and skill to produce, and to point out the inefficiency of the portfolios commonly in use. He then exhibited various handsome specimens of his ingenious and valuable contrivance, and pointed out their advantages, which were summed up as follows:—

1st. The mode of fastening, by hooks connected with elastic bands. It is not only simple but durable, and also most convenient; for by this contrivance the portfolio can be opened or closed in a moment, whereas the three or four pair of strings (the mode adopted in the old portfolio) require time and patience, and, besides, the tying and untying a few times so frets the woof parts of the strings, that they are soon torn off, leaving the sides of the portfolio unclosed.

2nd. Having the side-flaps on the outside. In this mode of arranging the flaps, you perceive there can be no damage to the edges of the contents of the portfolio by the strings cutting them; while, at the same time, there is a little pressure, drawing the flaps close to the sides.

3rd. At the corners, where dust could otherwise easily enter, you note the silk gussets, which effectually bar such deleterious influences. The elastic bands also serve to keep the bends of the flaps close to the edges of the portfolio.

4th. The back is suspended. By this mode the under edges of the works contained in the portfolio are effectually secured from being broken or bruised, as is always the case in the old kinds with limp backs.

5th. The side-flaps are on the outside. This advantage is twofold for whatever dust settles or dirt gathers on them can never enter within, which is not the case when they are made in the ordinary way and are placed on the inside.

6th. These flaps are got rid of, when desired, by simply reversing and hooking them on the side to which they are attached. In this position there can be no annoyance from their being in the way, and they cannot offend the taste by that unsightly and slovenly appearance which pertains to the old kinds. In fact, these protecting side-flaps, thus fastened, are out of sight, and the portfolio can be handled just as if there were none.

7th. The advantage just named applies only to those with supporting easels. By this addendum to the portfolio, the contents can be seen to the best possible advantage without their being removed from their places, just as you would turn over the leaves of a book; and at the same time a dozen persons can see them together, in the best manner without any inconvenience. The portfolio can also be placed at any required angle, and, in fact, can be made to serve itself as a table easel, on which you can incline a picture to copy, or a small canvass to paint on.

The eighth advantage is in those with locks. This gain on the old kinds, without locks, is, that you keep your collections from the curiosity of children and servants, as well as from theft, or borrowing friends who make free use with your works without first obtaining permission, and who frequently forget to return them. And to sum up all, which will make nine distinct and indispensable advantages of these patent portfolios, they are better looking, more elegant, and capable of being ornamented or finished to any degree of richness or cost.

PHOTOGRAPHY, AND THE INTERNATIONAL EXHIBITION OF 1862.

We have been favoured by Dr. Diamond with a copy of the correspondence between the Chief Barôn and Her Majesty's Commissioners, which we subjoin. We especially commend the manly and dignified letter of the Chief Baron to the attention of our readers, as worthily defining and defending the position of our art.

International Exhibition, 1862.
454, *West Strand, London, April* 26, 1861.

Sir,—I am directed by Her Majesty's Commissioners to forward for your information the inclosed copy of the decisions which they have published up to this date, on points relating to the management of tho Exhibition of 1862.

Her Majesty's Commissioners having had under consideration the arrangements that will be required for securing an adequate representation of the various branches of industry of the United Kingdom, and having had the benefit of the advice of a large and influential Committee whom they specially consulted on the subject, have determined to organise those classes of the Exhibition, which appear to admit of such an arrangement, by means of Central Committees, and to invite the cooperation of such Societies or other public bodies bodies, as are generally recognised as the representatives of these classes, in the selection of the members of the several Committees that will be appointed.

One of these Committees will bo formed in connexion with the Class of "Photographic Apparatus and Photography" (No. 14); and Her Majesty's Commissioners have directed me to inquire whether the Council of the Photographic Society would be willing to submit the names of six or eight gentlemen whom they would recommend for appointment as members of such Committee.

The duties of the Committee will consist generally in advising Her Majesty's Commissioners on tho measures to be taken for obtaining an adequate representation of the class with which it is connected—in examining the demands for space sent in by intending exhibitors, which will be classified and submitted to tho Committees in a condensed form by the officers of Her Majesty's Commissioners—in encouraging the production of suitable objects for exhibition—and in settling the final distribution of space among the exhibitors in the class.

Her Majesty's Commissioners trust that they may not only have tho assistance of your Council in tho selection of this Committee, but that the officers and members of your Society in general will give them the benefit of their co-operation, by communicating such information, or such results of their experience, as may seem likely to assist the Commissioners in those departments of the Exhibition with which the Photographic Society is mainly concerned.—I have the honour to be, Sir, your obedient servant, F. R. Sandford, *Secretary*.

Baron's Room, Court of Exchequer,
Westminster, 6th May, 1861.

Sir,—I have to acknowledge your communication of the 26th inst., *inquiring* whether the Council of the Photographic Society would be willing to assist in appointing a Committee to advise Her Majesty's Commissioners on the measures to be taken to procure an adequate representation of Photographic Apparatus and Photography, Class No. 14, and *expressing* "that Her Majesty's Commissioners trust that the Officers and Members of the Society will give the benefit of their co-operation, and assist tho Commissioners in those departments of the Exhibition with which the Photographic Society is mainly concerned."

I lost no time in assembling the Council, and laying before them your letter and its inclosuro (containing the decision as to Sections and Classes), and I have been desired by the Council to communicate to you the result of their deliberations, in which I entirely concur. It appears to them that some mistake has occurred with reference to the objects of the Photographic Society, indeed to photography itself, which it is desirable to point out and have corrected before they appoint a committee. Tho Class to which their attention is directed is Section 2, No. 14, "Photographic Apparatus and Photography" (as if photography were nothing more than the mero mechanical application or use of certain apparatus, and to be considered of less account than the apparatus itself).

The Section in which No. 14 is placed includes every species of machinery, implement, or tool which is used for the purposes of social life; and photography is the only *result* or *product*, which is placed among the machinery or apparatus necessary to produce it; it furnishes the solitary exception to what is otherwise a universal rule; even the paper on which a photograph is priuted is put into a section above the machine that is used to make it.

In the investigation of tho properties of light, upon which the visible phenomena depends, photography is as much a science as astronomy or chemistry; it has led to discoveries of the greatest interest and importance as to the composition of the rays of the sun, and the properties of the different portions of the solar spectrum, as was lately expressed in a part of Prof. Faraday's lecture at the Royal Institution. It has also enlarged the bounds of chemical science, by ascertaining the qualities of a great variety of substances with which it had to deal, and it is in these respects chiefly that I personally have any connexion with it.

In the observations of natural scenery, and in the selection of what shall be represented with referenco to the effect of light and shade, and from what point of view,—in the grouping and arranging of the principal or accessory objects for the purpose of forming a picture, photography is no doubt an art, *an imitative* art; but the Council of the Photographic Society claim for it a position (however humble) among the *fine arts* (if etching and engraving may be so placed, as no doubt *justly* they may). Photography, quite as much as engraving, gives room for the exercise of individual genius, so as to stamp a special character on the works of photographers, and give to the result of their labours the impress of the mind of each artist.

The Photographic Society has been founded chiefly with a view to promote photography in connexion with *science* and *the fine arts*, and the members interest themselves about photographic apparatus in the same manner only as a Raphael or a Reynolds might select and use the most convenient easel, the best brushes, or the most appropriate and enduring colours—the instrument is comparatively nothing. Photography consists in the artistic use of any apparatus upon a subject properly selected, and occasionlly arranged or prepared. They are quite willing to contribute as much as lies in their power to illustrate what photography has done, and is daily doing—In producing the most accurato copies of the finest works of art, ancient or modern,—in multiplying representations of the fairest or the wildest scenes of nature, and whatever art has done to adorn or improve nature in the building cities and constructing magnificent works and buildings of all sorts, from the cathedral or palace to the humblest cottage,—from the bridge that spans a mighty river to the plank that crosses a brook, or in giving enduring pictures of private and domestic life. They do not complain that the apparatus they use is put among all the other apparatus, but they do complain that results such as have been exhibited for many years by the Society, and have been honoured by the presence and encouragement of Her Majesty and His Royal Highness the Prince Consort, are deemed worthy of no better place than among tools and mechanical devices of whatever merit; and they would appeal to the Royal and illustrious patrons of their body to be rescued from the comparative degradation of being mixed up with the last improvement in ploughs or cart-wheels, or ship's tackle.

The very clear and luminous arrangement of the articles to bo exhibited, gives the greater force to the objection of the Council.

Section 1 contains all natural substances, whether mineral, vegetable, or animal, which minister to the wants and comfort of man.

Section 2 contains all the machinery and apparatus (including instruments and tools of every descriptiou) that conduce to a mechanical end; and, with one exception, it contains *nothing else*.

Section 3 contains the result produced by Section 2 acting upon Section 1.

There is something so remarkably distinct and simple in the arrangement, that it is to be regretted that its beautiful simplicity should be marred by any exception. But photography as a *result* is put in Section 2; it is the only thing that is out of place in the whole arrangement. A result that involves *thought, selection, taste*, and *sometimes design*, is put among carpenter's tools and agricultural implements! The incongruity is not so glaring, but it is of the same kind as if architecture were placed along with trowels and scaffolding, or Humboldt were put among commercial travellers.

Section 4 comprehends all that genius and labour have done in the departments by common consent called the fine arts, in which engraving has been *tardily* admitted.

But at last it *has* been admitted (now one of the latest discoveries in photography is) that an actual engraving (without the use of any graving tool) can be produced by chemical agency and the light of the sun. Is the impression from the result of such a process to be received as an engraving (which most undoubtedly it is)? and the other results of photography to be excluded? I am sorry to have troubled you at such length, but these are the views of the Council, which I have to submit to you in answer to your letter, and remain,—Your obedient Servant, Frederick Pollock.

To F. R. Sandford, Esq.,
Secretary of Her Majesty's Commissioners.
International Exhibition, 1862.

Proceedings of Societies.

Manchester Photographic Society.

The usual monthly meeting of this Society was held on the 1st inst., at the Philosophical Society's Rooms,—Mr. Joseph Sidebotham in the chair.

After some miscellaneous business, the subject of oblong stops was resumed.

Mr. Brothers, who had continued his experiments, exhibited some more specimens, showing chiefly the different degrees of intensity produced by the same simultaneous exposure with different stops, as suggested by Mr. Sidebotham, and said that there was no advantage derivable from the use of any but circular stops, as other stops drew out and distorted the lines in the direction of the stop.

The Chairman thought that such distortion was infinitely preferable to a distortion in every direction, as must be found to be the case with those who used five-inch lenses for portraiture. He had not brought forward his theory before he was as satisfied of its truth as of that of an axiom of Euclid. He thought Mr. Brothers' experiments should have been made on a smaller bust, and read a letter in the Photographic News, from Mr. Lake Price, in support of his theory, in reply to Mr. Maginn, who had discovered the same thing since the last meeting.

Mr. Brothers said he had nothing to allege against the theory, but thought the distortion was not visible to any great extent in portraits.

Mr. Wardley and Mr. Parry took some part in the discussion.

Mr. Noton produced four pictures taken with a longitudinal, an upright, a triangular, and a circular aperture. The preference appeared to be given to the one with the perpendicular stop, though the triangular one would probably have given the best effect had the opening not extended too much into the margin of the lens. The object was a perpendicular gothic monument of the late Joseph Brotherton. He said his object in experimenting in that direction was to find a means to shut off any superfluous sky, which was sometimes very desirable.

The Chairman said that the contracted oblong stops were of course not applicable to landscapes.

A discussion ensued upon the pictures on the table, by Messrs. Petschler and Mann's process, which many who had used the old Taupenot process agreed were fully equal to any that could be produced by it.

Mr. Petschler promised, on being requested by the Chairman, to develop one of his plates at the next meeting. He used, he said, three grains of pyrogallic acid to the ounce, and two or three minims of a ten-grain solution of nitrate of silver. When the details began to appear he reduced the strength of the pyrogallic acid, and added more silver. Five to ten minutes sufficed to develop a picture 9 × 7. The copies of engravings had had three-quarters of an hour's exposure with a half-inch stop.

Mr. Parry explained that, in his process, a neutral silver bath caused fogging, and this effect had made Dr. Ryley condemn the process—probably without knowing the cause. He (Mr. Parry) found that he got the best results from an acid bath.

The Chairman reported very favourably as to the copying capabilities of one of Dallmeyer's lenses which he had been trying: the caricature on the table was a specimen. He also begged an inspection of Mr. Noton's very ingenious pneumatic plate-holder, one of which was on the table.

A miscellaneous conversation ensued, after which it was announced by the Chairman that the Committee had made arrangements with the General Committee for a Photographic Exhibition, to be held on the occasion of the visit of the British Association, in August next. A sum of money had been granted for that purpose. One of the best rooms in the Royal Institution had been obtained, and, with the time and money they had at command, he did not doubt that they would be able to get up an Exhibition superior to anything of the kind which had preceded it. He suggested to the members the desirability of their taking improved views of places of interest in the neighbourhood.

Birmingham Photographic Society.

The ordinary monthly meeting of this Society was held at the Odd Fellows' Hall, Temple Street, on Tuesday, the 30th ult., W. B. Osborne, Esq., Vice-President, in the chair.

After some miscellaneous business, and the exhibition of several specimens, a discussion on lenses was resumed, and much interesting information elicited.

Mr. Turner produced three portraits, the negatives of which he stated were taken by one of Lerebour's small lenses. He stated that he found the Lerebour lens to work better than any other he could obtain, as it would cover a large picture equally with a smaller one, without any distortion or weakness towards the edges.
